overlap considerably with those of Noonan and CFC syndromes, and it may be difficult to distinguish these syndromes based on newborn appearance. Later in childhood, the skin papules and graying hair can be diagnostic of Costello syndrome. Genetic testing for *HRAS* mutations is available for a definitive diagnosis.

Treatment and management

Individuals with Costello syndrome require extensive treatment and management throughout life to address multiple physical and intellectual conditions as they arise. Children will require special education and treatment by a team of specialists.

Heart disease is seen in almost half of individuals with Costello syndrome. The heart problems are sometimes apparent at birth. These include holes in the muscular wall of the heart, abnormal thickening of the walls of the heart, and an abnormal heartbeat or arrhythmia. An echocardiogram (ultrasound of the heart) is usually performed early in life to assess heart function. Heart function is closely monitored as patients age.

Individuals with Costello syndrome frequently develop rare types of cancer. These cancers may occur early in life, even in infancy. Therefore, continual cancer surveillance throughout life is required.

Prognosis

The severe problems with feeding and growth that characterize Costello syndrome can be life-threatening. Most of these infants require a feeding tube to survive. Complications of heart disease are another life-threatening

concern, even in early life. For most individuals, the heart problems are not severe and usually can be successfully treated without surgery, although some individuals with Costello syndrome have experienced heart failure and sudden death. Lastly, individuals with Costello syndrome are at risk for developing and possibly dying of cancer.

Cowden syndrome

Definition

Cowden syndrome is a rare genetic disorder whose main symptom is the presence of many benign (noncancerous) growths that are known as hamartomas. People with Cowden syndrome have a higher risk of developing certain types of cancers.

Description

Because Cowden syndrome is caused by mutations in the *PTEN* gene, it is often referred to as *PTEN* hamartoma tumor syndrome, along with other disorders caused by *PTEN* mutations, including Bannayan-Riley-Ruvalcaba syndrome and Cowden-like syndrome. Most people with Cowden syndrome have hamartomas on the skin and mucous membranes. Hamartomas also may occur inside the body, such as within the intestines.

Because people with Cowden syndrome are at high risk for developing certain types of cancer, it is considered a familial or hereditary cancer syndrome.

- Women with Cowden syndrome have an estimated 85% lifetime risk of developing breast cancer.
- Men and women are at a 10% risk of developing cancer of the thyroid.
- Women have a 5%–10% chance of developing cancer of the endometrium (uterine lining).

Women with Cowden syndrome may also develop benign disorders of the breast, including a 67% risk of fibrocystic breast disease. Men and women have a 75% chance of developing benign conditions of the thyroid, such as goiter or benign tumors. They are also more likely than the general population to have polyps in the stomach, small intestine, or colon; fibroids in the uterus; and lipomas (fatty tumors) and hemangiomas (tumors involving blood vessels).

PTEN (Phosphatase and TENsin homolog) is a member of the protein tyrosine phosphatase (PTP) gene family. It encodes the instructions for making a PTP protein that is found almost everywhere in the body. The *PTEN* protein is a tumor suppressor that regulates cell division to prevent cells from growing and dividing uncontrollably. The *PTEN* protein is an enzyme that removes a phosphate (PO₃) group from other proteins and from fats (lipids) as part of a cell-signaling pathway that instructs cells to stop growing and dividing, and/or triggers cells to self-destruct (apoptosis). Thus, mutations in the *PTEN* gene that result in the dysfunction or lack of the *PTEN* protein can cause cells to grow and divide uncontrollably, leading to the formation of benign and cancerous tumors in various parts of the body. The *PTEN* protein may also help control cell migration (movement), adhesion (sticking) of cells within tissues, and the formation of new blood vessels (angiogenesis). In addition, the *PTEN* protein may help maintain the stability of the genetic information within a cell. As a result of these multiple roles, *PTEN* mutations can cause a variety of problems throughout the body.

KEY TERMS

Apoptosis—Programmed cell death.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Endometrium—Lining of the uterus.

Hamartomas—Masses resembling tumors.

Hemangioma—A benign growth in a blood vessel.

Keratosis—Horny overgrowths of skin.

Lhermitte-Duclos disease—A rare form of benign brain tumor.

Lipomas—Benign fatty tumors.

Macrocephaly—A larger-than-normal head.

Protein tyrosine phosphatase (PTP)—A member of a protein family, including the *PTEN* protein, that modifies other proteins by removing a phosphate group.

PTEN—The gene that encodes a protein tyrosine phosphatase that is a tumor suppressor active in nearly all cells of the body; mutations in *PTEN* result in Cowden syndrome.

Genetic profile

The *PTEN* gene is located on the long arm (q) of chromosome 10 at position 10q23.3. More than 300 different mutations in the *PTEN* gene have been identified as causing Cowden syndrome, Cowden-like syndrome, or Bannayan-Riley-Ruvalcaba syndrome. These mutations range from small changes in the DNA sequence of *PTEN*, to large deletions within the gene. They cause a dysfunctional or abnormally functioning *PTEN* protein that fails to inhibit cell division or signal apoptosis in abnormal cells, resulting in hamartomas and cancerous tumors.

PTEN mutations are inherited in an autosomal dominant pattern. This means that only one mutated copy of the *PTEN* gene, inherited from one affected parent, is required to develop Cowden syndrome. Each child of an affected parent has a 50% risk of inheriting the mutated gene and the disorder. About 15% of *PTEN* mutations occur sporadically in an individual in whom neither parent carries the mutated gene. If the mutation occurs later in development, it may be present in only some of the cells in the body (mosaicism). If the mutation occurs in germline cells (eggs or sperm), it can still be passed on to that individual's offspring. However, *PTEN* mutations generally affect every cell in the body. Genetic screening can detect *PTEN* mutations.

Demographics

Cowden syndrome is extremely rare, occurring in approximately 1 in every 200,000 people. Because Cowden syndrome is not easily diagnosed, its true prevalence may be higher. The characteristic growths of Cowden syndrome usually appear before the age of 30. The disorder affects males and females equally.

Signs and symptoms

Symptoms of Cowden syndrome include hamartomas and cancers of the breast, thyroid, and uterine lining. Other symptoms may include:

- macrocephaly, a larger-than-normal head
- Lhermitte-Duclos disease, a rare benign brain tumor
- intellectual deficiencies

Diagnosis

Diagnosis of Cowden syndrome is very important because of the heightened risk of cancer and because symptoms may not appear until adulthood. Diagnosis allows for regular screenings to detect cancers early when they are more likely to be cured. Diagnosis may also alert other family members to the need to be screened for Cowden syndrome and cancers.

Examination

Clinical diagnosis may be based on presence of the characteristic skin lesions, the most notable being those on the face and mucous membranes. Facial papules (known as trichilemmomas) and keratoses (overgrowths of horny tissue) on the hands—including the palms—and mucous membranes affect 90% of people with Cowden syndrome. The healthcare practitioner notes the type of lesions, number of lesions, and their locations. Because thyroid disease occurs in approximately two-thirds of patients with Cowden syndrome, the thyroid is carefully examined. Inside the mouth, a characteristic pattern of cobblestone-like growths is apparent in approximately 40% of patients with this disorder.

Genetic testing

Genetic testing involves a blood test to detect known mutations in the *PTEN* gene. Because some mutations may not be detected by genetic testing, a negative test does not necessarily rule out Cowden syndrome. If a gene mutation is identified, other family members may have predictive testing to determine if they are at risk for developing tumors.

QUESTIONS TO ASK YOUR DOCTOR

- Should I have genetic testing for Cowden syndrome?
- Should my family members have genetic testing?
- What is my risk of having a child with Cowden syndrome?
- What cancer screenings do you recommend, and how often?
- Do you recommend annual mammography or MRI for breast cancer screening?

Treatment and management

Traditional

While there is no cure for Cowden syndrome, diligent management can help ensure that cancers are detected at an early stage. Even in the absence of symptoms, people with Cowden syndrome are advised to undergo regular cancer screenings.

- Breast cancer screenings include a monthly breast self-exam for men and women, yearly clinical breast exams for women aged 25 and over, and yearly mammograms for women beginning at ages 30 to 35 (or 5 to 10 years prior to the youngest diagnosis of breast cancer in the family). The American Cancer Society recommends that women with Cowden syndrome have annual breast screenings by magnetic resonance imaging (MRI).
- Men and women should have their first ultrasound screening for thyroid cancer at age 18 and possibly subsequent screenings on a yearly basis.
- Women should be screened for uterine cancer by uterine biopsy, beginning at age 35–40, and yearly uterine ultrasounds after menopause with biopsies of any suspicious growths.
- Men and women with a family history of kidney cancer should have annual urinalysis, urine cytology, and ultrasound of the kidney.

Treatment for skin lesions may include dermatological procedures such as chemical peels, laser resurfacing, or cryosurgery. In some cases, the lesions may be removed via surgery or shave excisions. Complications with keloid formation (scarring) may arise after surgery, so surgical intervention is avoided unless dermatological manifestations cause significant pain or deformity.

Drugs

Oral retinoids may offer temporary control of skin lesions; however, the growths usually reappear when the drug is discontinued.

Prognosis

People with Cowden syndrome have a significantly higher risk for developing cancers, particularly cancers of the breast, thyroid, and uterus. Breast cancer in women with Cowden syndrome develops, on average, between the ages of 38 and 46. Thus, a diligent schedule of cancer screenings is very important for a good prognosis. Individuals with Cowden syndrome and their siblings and offspring should undergo genetic counseling and testing, both for diagnosis and for family planning purposes, including preconception counseling and pre-implantation or prenatal diagnosis.

Crane-Heise syndrome

Definition

Crane-Heise syndrome is a lethal genetic disorder first defined in 1981. Some of the features of Crane-Heise syndrome are similar to those of another genetic disorder called aminopterin syndrome sine aminopterin (or pseudoaminopterin syndrome), indicating that the two conditions may be part of a spectrum of symptoms.

Description

Aminopterin syndrome is an established disorder resulting from the use of aminopterin as an abortifacient. Surviving infants who had been exposed to this chemical had severe developmental abnormalities, especially those of the skull. Crane-Heise is distinct from aminopterin syndrome in that the mothers of infants with Crane-Heise syndrome were not exposed to aminopterin.

Genetic profile

There are only nine documented cases of Crane-Heise syndrome, and therefore little is known about the genetic basis of the disorder. One candidate gene that may be associated with the syndrome is *FGDI*, located on the X chromosome at p11.21.

Since Crane-Heise syndrome has affected more than one sibling in a family and has been seen in both males and females, it is most likely transmitted through autosomal recessive inheritance. This means that two copies of the abnormal gene would have to be inherited, one from each parent, in order for the disorder to occur.

Demographics

Males and females are at equal risk for inheriting Crane-Heise syndrome since it is assumed to be an autosomal trait, meaning it is not inherited on one of the sex-determining chromosomes. No one ethnic group has been shown to be at higher risk, primarily due to the low number of reported cases. Of the cases reported, there tends to be a frequent recurrence of the disease with each pregnancy.

Signs and symptoms

Many distinct characteristics are seen in infants with Crane-Heise syndrome. Some of these include the following:

- large head with a relatively small face
- depressed nose with nasal openings turned forward
- underdeveloped jaw
- a narrow nose bridge with eyes close together

KEY TERM

Autosomal recessive—A pattern of genetic inheritance in which two copies of an abnormal gene are needed to display the trait or disease.

QUESTIONS TO ASK YOUR DOCTOR

- What is the likelihood of survival for a fetus with Crane-Heise syndrome?
- What information can a genetic counselor provide about the possibility of my having a child born with Crane-Heise syndrome?
- What treatments are available for a child born with this disorder?

- low-set ears that are turned to the back
- short neck
- partially fused fingers or toes
- clubfoot

The most definitive features of Crane-Heise syndrome and aminopterin syndrome are the cranial and bone abnormalities. Infants born with these syndromes typically have absent or underdeveloped brains (anencephaly), underdeveloped shoulder blades, and absent collarbones and vertebrae.

Diagnosis

Since the signs of Crane-Heise syndrome are nearly identical to those observed in infants with aminopterin syndrome, it is important to identify whether the mother was exposed to aminopterin for differential diagnosis. Some fetuses have been diagnosed with Crane-Heise syndrome in the uterus via ultrasonography; however, most diagnoses are based on physical examination at the time of birth.

Treatment and management

As of 2021, no treatment had been developed. Further research to better understand the cause and genetic basis of this disorder is necessary.

Prognosis

Crane-Heise syndrome is a lethal disorder, and infants are usually stillborn or survive only a few days

after birth. Malformations of the brain and vertebrae are usually severe and cannot be corrected surgically.

Craniofacial microsomia

Definition

Craniofacial microsomia is a general diagnosis used to describe facial birth defects of varying severity that may involve certain differences in the eyes, ears, facial bones, jaw, mouth, neck, or spine. These defects often affect only one side of the face, with that side appearing smaller than the other.

Description

Individuals with craniofacial microsomia have physical differences that are present at birth (congenital). These abnormalities are typically limited to the head and bones of the spinal column (vertebrae) and may be severe or mild. In some cases, the changes are seen on both sides of the face (bilateral). In other cases, they are limited to one side of the face (unilateral).

Different terms may be used for this pattern of differences. Craniofacial microsomia may also be called hemifacial microsomia, first and second branchial arch syndrome, Goldenhar syndrome, otomandibular dysostosis, facioauriculovertebral sequence, or oculo-auriculo-vertebral spectrum (OAVS). This final name describes

the common birth defects seen in persons with craniofacial microsomia. “Oculo” refers to the eye, and “auriculo” refers to the ear. Finally, “vertebral” refers to the physical problems present in the vertebrae.

Genetic profile

Craniofacial microsomia is caused by a disruption of normal facial development. A baby’s face forms very early, normally between the eighth and twelfth weeks of pregnancy. Normal facial development depends on many different tissues growing together in the correct order. When the movement and development of these tissues is disrupted, the face may have abnormal openings, underdevelopment of some facial features, and/or excess skin. In craniofacial microsomia, some unknown event disrupts normal development of the first and second branchial arches, the embryonic structures that later develop into the sides of the face, the jaw, and the upper neck.

There are most likely many different factors that may lead to the abnormal development of the facial tissues. In some cases, these factors may be environmental. For example, there are certain medications a woman can take while pregnant that can cause the baby to have the symptoms of craniofacial microsomia. However, in the vast majority of cases, craniofacial microsomia is not caused by a medication or drug of abuse consumed during pregnancy.

In other cases, normal development of the facial tissues may be disrupted by genetic factors. Unlike some other syndromes, there has been no single gene mutation identified that causes craniofacial microsomia. Studies in a few persons with craniofacial microsomia point to a possible candidate gene located on the long arm of chromosome 14 at 14q32; however, this finding requires further study and characterization. Another group of researchers in Italy reported in 2015 on a patient with OAVS found to have a microduplication on the long arm of chromosome 3 at 3q29. This microduplication, however, involved nine separate genes, any of which might be identified in the future as associated with craniofacial microsomia. In addition, further research is required to determine whether this specific genetic abnormality can be identified in a larger population than a single patient.

A few families in which craniofacial microsomia occurs show an autosomal recessive inheritance pattern, while other families show an autosomal dominant pattern of inheritance. Most cases of craniofacial microsomia are not inherited.

Craniofacial microsomia typically occurs sporadically (at random). Doctors are often unable to explain why it occurs. Since it is sporadic in nature, if a child is diagnosed with craniofacial microsomia, the risk for the parents to have another child with the disorder is low,

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a non-sex chromosome is required for a disease or inherited trait to develop in an individual.

Autosomal recessive—A pattern of genetic inheritance in which two copies of an abnormal gene are needed to display the trait or disease.

Branchial arches—Structures that form during the development of the human embryo as outpouchings of the developing pharynx. The first and second branchial arches in humans give rise to the bony and muscular structures of the face, jaw, and upper neck.

Coloboma—A birth defect in which part of the eye does not form completely and appears to be cleft or notched.

Congenital—Refers to a disorder that is present at birth.

Dysostosis—A general term for a disorder of bone development.

Mandible—The lower jaw bone.

Maxillae—The two facial bones that fuse to form the upper jaw and the roof of the mouth in humans.

Microduplication—A condition in which a small amount of genetic material is abnormally copied in a chromosome, usually a dozen genes or fewer.

Microphthalmia—A developmental disorder of the eye in which one or both eyes are smaller than normal and have other structural defects.

Microsomia—A general term for an abnormally small body or body part.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than ten degrees to the right or left as the doctor faces the patient.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

about 3%. In rare cases, one parent or another family member may have some of the physical symptoms of craniofacial microsomia. If this is the case, then the risk of having a child with the disorder may be higher, and the parents should consult a genetic counselor.

Demographics

Craniofacial microsomia is a relatively common congenital disorder; it occurs once in every 3,000–5,000 live

births. Other researchers estimate that the disorder is much less common, affecting only one child in 26,550. One reason for this discrepancy is that doctors do not agree on the criteria for diagnosing craniofacial microsomia. Another reason is that mild cases might not come to a doctor's attention. Males are affected more frequently than females: some researchers give a sex ratio of two males to one female. Craniofacial microsomia is seen in all ethnic groups and cultures.

Signs and symptoms

The symptoms associated with craniofacial microsomia are highly variable. Some individuals have many severe abnormalities, while others have only a few minor birth defects.

The abnormalities seen in craniofacial microsomia are typically limited to the face and vertebrae. Thirty percent of patients have bilateral facial abnormalities. In those patients, the right side is usually affected more severely. The facial asymmetry commonly observed in persons with craniofacial microsomia is caused by hypoplasia (underdevelopment) of the upper and lower jaw. These bones are called the mandible (lower jaw) and the maxillae (two bones in humans that fuse to form the upper jaw and the roof of the mouth). In addition to the bones of the face, the muscles of the face can also be underdeveloped. Cleft lip and cleft palate are other facial differences associated with craniofacial microsomia. Cleft lip is an abnormal split or opening in the lip that can extend toward the nose or toward the cheek. Cleft palate is an opening in the roof of the mouth. Individuals with craniofacial microsomia can also have an unusually wide mouth (macrostomia).

Birth defects of the eye are common in craniofacial microsomia. Cysts on the eyeball (epibulbar dermoids) are common, as is microphthalmia (small eye). Some individuals with Goldenhar syndrome have a notch of tissue missing from the upper eyelid (coloboma). Strabismus (crossing of the eyes) is also prevalent.

Abnormal development of the ears is another characteristic of the craniofacial microsomia spectrum. The ears may be smaller than normal (microtia), or absent (anotia). Ear tags (excess pieces of skin) may be seen on the cheek next to the ear and may extend to the corner of the mouth. The shape of the ears may also be unusual. Hearing loss is common in individuals with craniofacial microsomia.

The vertebral anomalies seen in many persons with craniofacial microsomia result from improper development of the vertebrae. Vertebrae can be incompletely developed (hemivertebrae), absent, or fused. Ribs can also be abnormal. Approximately 50% of individuals

QUESTIONS TO ASK YOUR DOCTOR

- Do you think that the gene or genes associated with craniofacial microsomia will be identified in the near future?
- Can you recommend a children's hospital with experienced specialists who can treat my child's craniofacial microsomia?
- How can we help our child cope with the outward signs of his disorder as he or she grows older?
- What are the chances that we or other family members will have another child with craniofacial microsomia?

with craniofacial microsomia will have side-to-side curvature of the spine (scoliosis).

Other differences outside the face and vertebrae can occasionally be seen in craniofacial microsomia. Approximately 15% of individuals with craniofacial microsomia have developmental delays or intellectual disability. The likelihood of intellectual disability increases if the individual has microphthalmia (abnormally small eyes). Heart defects and kidney defects can occur. Arm defects, though rare, may also occur.

Diagnosis

The diagnosis is made when an individual has the common symptoms associated with the condition. It can be made before birth by a physician using ultrasound imaging, or after birth on the basis of the observed physical features. Although it is not universally accepted, one scale used by many doctors in the United States for evaluating the severity of craniofacial microsomia is the OMENS scale (Orbital distortion, Mandibular hypoplasia, Ear anomaly, Nerve involvement, and Soft tissue deficiency). The scale was introduced in 1991 by a team of doctors at Harvard Medical School.

Treatment and management

Once a child is diagnosed with craniofacial microsomia, additional tests should be performed. The parents should consider having their child evaluated and treated at a specialized children's hospital with a craniofacial center. A hearing evaluation is necessary to determine whether there is hearing loss. If hearing loss is evident, the child should be referred to a hearing specialist. Speech therapy may be helpful. X-rays of the spine are

recommended to determine whether there are vertebral problems. Individuals with craniofacial microsomia may be followed regularly to check for scoliosis. Ultrasounds of the kidneys and heart may be recommended, due to the increased risk of birth defects in those organs. A doctor would make this recommendation. Finally, individuals with craniofacial microsomia should be evaluated by an eye specialist (ophthalmologist).

Surgery may be necessary to correct the birth defects seen in craniofacial microsomia. Surgery to correct the facial birth defects can improve the child's appearance and function. As the child approaches school age, psychological counseling may be beneficial to assist him or her in coping with the social challenges presented by abnormal facial features or postural problems.

Prognosis

The prognosis for individuals with craniofacial microsomia is very good. These individuals typically have a normal lifespan and normal intelligence.

Craniosynostosis

Definition

Craniosynostosis is a congenital abnormality of the central nervous system that involves the premature closing of one or more of the fibrous joints between the bones of the skull (cranial sutures).

Description

Craniosynostosis is a birth defect that affects the shape of the skull. Because there are several different types of this defect, some doctors refer to them in the plural as the craniosynostoses. Individuals born with craniosynostosis have abnormally shaped heads and a prominent bony ridge over the affected suture or sutures. All affected individuals also are likely to experience water on the brain (hydrocephalus), which can cause enlargement of the head and increased pressure inside the skull. Developmental delay is commonly experienced by those individuals affected by craniosynostosis.

Craniosynostosis

Different types of craniosynostosis (Gale)

There are two major classifications of the craniosynostoses: primary and secondary. There are multiple causes of primary craniosynostosis, which involves abnormal cranial suture development. The premature closure of one or more of the sutures causes the skull bones to grow parallel to the affected suture but not perpendicular to it. At other sutures there may be too much growth. The disrupted growth patterns cause a misshapen skull. The cause of secondary craniosynostosis is failure of the brain to grow and expand. This failure results in uniform premature suture closure so that the head is symmetric and abnormally small (microcephalic).

The human skull consists of several bony plates separated by a narrow gap that contains stem cells. These fibrous joints are referred to as cranial sutures. There are six cranial sutures: the sagittal, which runs from front to back across the top of the head; the two coronal sutures, which run across the skull parallel to and just above the hairline; the metopic, which runs from front to back in front of the sagittal suture; and the two lambdoid sutures, which run from side to side across the back of the head. There are seven types of primary craniosynostosis classified according to the cranial suture or sutures that are

affected: sagittal; bicoronal (both coronal sutures); unicoronal (one coronal suture); coronal and sagittal; metopic; lambdoid and sagittal; and total, in which all the cranial sutures are affected. Approximately 40% of all cases of craniosynostosis are sagittal; 20% are bicoronal; 15% are unicoronal; 10% are coronal and sagittal; 4% are metopic; 1% are lambdoid and sagittal; and 10% are total.

Genetic profile

Craniosynostosis does not have a single genetic cause, but it is sometimes passed from one generation to another. It has been associated with over 150 different genetic syndromes. Genetic inheritance of craniosynostosis is not sex-linked (it is autosomal), and it has been tied to both dominant and recessive patterns of inheritance. The overall occurrence rates are equivalent between males and females, but sagittal craniosynostosis is seen four times as often in males as in females, while coronal craniosynostosis is observed twice as often in females as in males.

Craniosynostosis is known to be marked by genetic heterogeneity, which means that more than one gene or

genetic mechanism can produce the disorder. Three of the genes associated with craniosynostosis—at chromosome locations 8p11.23-p11.22 (*FGFR1*), 10q26 (*FGFR2*), and 4p16.3 (*FGFR3*)—are related to fibroblast growth factor receptors (*FGFRs*), which are molecules that control cell growth. Mutations in these genes are linked to such syndromes as Muenke syndrome, Apert syndrome, Crouzon syndrome, and others in which craniosynostosis is one feature among others (limb defects, hearing loss, developmental delays, deformed facial features, etc.) These known genetic syndromes account for about 10% to 20% of reported cases of craniosynostosis.

In addition to the *FGFR*-related genes, four other genes had been linked to craniosynostosis as of 2021. These forms of the disorder are presently classified as types 1 through 4; all are relatively rare:

- Craniosynostosis type 1 (CRS1) is caused by a mutation in the *TWIST1* gene on the short arm of chromosome 7 at 7p21 and is inherited in an autosomal dominant pattern. The mutation causes coronal and sagittal forms of the disorder.
- Craniosynostosis type 2 (CRS2) is caused by mutations in the *MSX2* gene on the long arm of chromosome 5 at 5q35.2. This mutation also is inherited in an autosomal dominant fashion.
- Craniosynostosis type 3 (CRS3) is caused by mutations in the *TCF12* gene on the long arm of chromosome 15 at 15q21.3. Type 3 craniosynostosis occurs in several different forms, including coronal, sagittal, and multi-suture presentations.
- Craniosynostosis type 4 (CRS4) is caused by mutations in the *ERF* gene on the long arm of chromosome 19 at 19q13.2. Type 4 craniosynostosis has the widest variety of presentations, with sagittal, metopic, lambdoid, coronal, and multisuture craniosynostoses being reported in different families with the mutations.

Not all instances of craniosynostosis appear to have a genetic origin. The most common cause of nongenetic craniosynostosis is constraint of the fetal head during pregnancy. This condition is believed to account for between 50% and 60% of all cases of craniosynostosis.

Demographics

Craniosynostosis has an incidence of approximately 1 in every 2,200 live births. Genetic-based craniosynostosis is most commonly a dominant trait, but in some cases it has also been shown to be recessive. Therefore, while it is more likely to occur in children with a family history of craniosynostosis, it may not occur in the children of such families and it may also occur in children with no family history of the disorder. Nongenetic craniosynostosis has a higher occurrence among the children of malnourished or

KEY TERMS

Acrocephalopolysyndactyly syndromes—A collection of genetic disorders characterized by a cone-shaped abnormality of the skull and partial fusing of adjacent fingers or toes.

Acrocephaly—An abnormal cone shape of the head.

Anterior fontanelle—The soft spot on the skull of an infant that is located in the center of the head just behind the hairline.

Brachycephaly—An abnormal thickening and widening of the skull.

Congenital—Refers to a disorder that is present at birth.

Cranial suture—Any one of the seven fibrous joints between the bones of the skull.

Frontal plagiocephaly—An abnormal condition of the skull in which the front is more developed on one side than it is on the other side.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain, often causing enlargement of the head.

Microcephalic—Having an abnormally small head.

Primary craniosynostosis—Abnormal closure of the cranial sutures caused by an abnormality in the sutures themselves.

Proptosis—Bulging or protruding eyeballs.

Scaphocephaly—An abnormally long and narrow skull.

Secondary craniosynostosis—Abnormal closure of the cranial sutures caused by a failure of the brain to grow and expand.

Trigonocephaly—An abnormal development of the skull characterized by a triangle-shaped forehead.

drug-abusing mothers. It is also more likely to occur in the children of teenage mothers because of the lack of development of an appropriately sized uterus for fetal growth in many of these cases.

Signs and symptoms

The most obvious symptom of craniosynostosis is an abnormally shaped head that is not the result of the birth process. Craniosynostosis may be confirmed by the presence of a bony ridge over the affected cranial suture. Associated symptoms include such unusual facial

features as wide-set, down-slanting, or protruding eyes and a prominent jaw; visual impairment; hearing loss; breathing problems; water on the brain (hydrocephalus); and developmental delay.

Each type of craniosynostosis has different physically observable symptoms and results in a different head shape. Sagittal craniosynostosis is characterized by a long and narrow skull (scaphocephaly). This is referred to as an increase in the A-P, or anterior-to-posterior, diameter. Thus an observer looking down on the top of the skull would see that the diameter of the head is greater than normal in the front-to-back direction. Individuals born with sagittal craniosynostosis have broad foreheads and a larger-than-normal back of the head. The so-called soft spot found just beyond the hairline in a normal baby (the anterior fontanelle) is missing or very small in a baby affected with sagittal craniosynostosis. The result of neurological testing is generally normal for individuals with sagittal craniosynostosis.

Bicoronal craniosynostosis is characterized by a wide and short skull (brachycephaly) or by a cloverleaf-shaped skull. This feature is referred to as a decrease in the A-P diameter. Individuals affected with bicoronal craniosynostosis have poorly formed eye sockets and foreheads. This characteristic causes a smaller-than-normal eye socket that can lead to visual complications. These complications include damage to the optic nerve, which can cause a loss of visual clarity; bulging eyeballs (a condition called proptosis), which usually results in damage to the cornea; widely spaced eyes; and a narrowing of the sinuses and tear ducts that can cause inflammation of the mucous membranes lining the exposed portion of the eyeball (conjunctivitis). Bicoronal craniosynostosis can be further complicated by water on the brain (hydrocephalus) and increased intracranial pressure. Most individuals affected with bicoronal craniosynostosis also have an abnormally high and arched palate that can cause dental problems and protrusion of the lower jaw. Bicoronal craniosynostosis is associated with several acrocephalosyndactyly syndromes (genetic syndromes that involve abnormalities of the head and webbed fingers or toes), which include Apert syndrome, Apert-Crouzon syndrome, Saethre-Chotzen syndrome, and Pfeiffer syndrome.

Unicoronal craniosynostosis is characterized by a skull that is more developed in the front on one side than it is on the other side (frontal plagiocephaly). This characteristic leads to a distinct asymmetry between the sides of the face, a flattening of the forehead on the side affected by the premature suture closure, and a misalignment of the eyes such that the eye on the affected side is higher than the eye on the unaffected side.

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “craniosynostosis” mean?
- How do the primary and secondary craniosynostoses differ from each other?
- Can craniosynostosis be diagnosed with prenatal imaging and genetic tests?
- What kind of surgical procedures are available for dealing with craniosynostosis in an infant, and how successful are those procedures at present?

Coronal and sagittal craniosynostosis is characterized by a cone-shaped head (acrocephaly). The front soft spot (the anterior fontanelle) is generally much larger than normal, and it may never close without surgical intervention. Individuals affected with coronal and sagittal craniosynostosis may have higher than normal intracranial pressure. Pfeiffer syndrome is closely associated with coronal and sagittal craniosynostosis.

Total craniosynostosis is characterized by a normally shaped but small skull (microcephaly). Individuals affected with total craniosynostosis have higher than normal intracranial pressure, and they are the most likely of all craniosynostosis-affected individuals to suffer from developmental delay.

Metopic craniosynostosis is characterized by a triangle-shaped forehead (trigonocephaly), thickened bones in the forehead, and narrowly spaced eyes. Individuals affected with metopic craniosynostosis tend to have developmental abnormalities associated with processes that are known to be controlled by the front of the brain (the forebrain).

Lambdoid and sagittal craniosynostosis is the rarest type of craniosynostosis. It is characterized by a flattening of the back of the skull (the occipital bone) and a bulging of the front of the skull (the frontal bone). This condition may occur symmetrically or asymmetrically.

Diagnosis

Prenatal, transabdominal, or traditional ultrasound can be used to assess fetal skull development in the second and third trimesters of pregnancy; however, a CT scan is considered the most accurate diagnostic imaging test for prenatal diagnosis of craniosynostosis. Plain radiographic studies may also be performed. Bicoronal

and unicoronal craniosynostosis associated with one of the acrocephalosyndactyly syndromes may be detected via several different genetic tests. These tests are able to identify the underlying mutations in all three *FGFR* genes and the genes that are linked to craniosynostosis types 1, 2, and 4. In 2019, Fulgent Genetics in California introduced a single gene test for the gene associated with craniosynostosis type 3.

Almost all cases of craniosynostosis are evident at birth; however, the cranial sutures are not fully closed at this time, so instances of craniosynostosis have been diagnosed later in infancy as well. Skull x-rays and/or a CT scan may also be used after birth to diagnose craniosynostosis.

Treatment and management

Because craniosynostosis is associated with other conditions and may require multiple treatments of the skull, face, eyes, and ears, a multidisciplinary team of doctors and specialists is often required. The skull abnormalities of craniosynostosis should be surgically corrected within the first year of life. In the first year of life, changing the elevation and contours of the skull bones is much easier, and new bone growth and reshaping occur rapidly. Also, at this point the facial features are still highly undeveloped, so significant improvement in appearance can be achieved.

Multiple surgeries may be required over the patient's lifetime, depending on the circumstances of the case. Follow-up support by pediatric, dental, psychological, neurological, surgical, and genetic specialists may be necessary.

In the types of craniosynostosis that involve the eyes, consultation with an ophthalmologist is often recommended, and eye surgery may also be necessary. Speech and hearing therapy may also be needed when the ears and the frontal lobe have been affected. In the case of bicoronal craniosynostosis in which the palate is severely malformed, dental consultation may also be required. In the most severe cases of coronal craniosynostosis, it will be necessary to address feeding and respiratory problems that are associated with the abnormally formed palate and sinuses.

Families with a history of craniosynostosis can participate in genetic counseling in order to learn whether genetic testing can identify the likelihood that their children might be affected.

Prognosis

In all but the most severe and inoperable cases of craniosynostosis, it is possible that considerable

improvement in physical appearance can be achieved via surgery. Depending on the neurological damage resulting from certain types of craniosynostosis versus the rapidity of treatment, certain affected individuals may suffer developmental disabilities ranging from the extremely mild to very severe. Most individuals with craniosynostosis that involves coronal sutures will continue to have vision problems throughout life. These problems vary in severity, but many are now amenable to fully corrective treatments.

Creutzfeldt-Jakob disease

Creutzfeldt-Jakob (pronounced KROYTZ-felt YAH-kob) disease (CJD) is a rapidly progressive neurodegenerative disorder that has no cure and ends in death, often within a matter of months. It is named for Hans Gerhard Creutzfeldt and Alfons Maria Jakob, two German neuropathologists who first reported it in a series of four patients in 1920 and 1921.

CJD is a very rare disease of the central nervous system caused by a prion, or a misfolded protein that can convert normal proteins to its abnormal shape. The term “prion” was coined in 1982 by Stanley Prusiner, an American neurologist, to describe these unusual disease agents that can replicate and cause transmissible disease, even though they lack the nucleic acids found in bacteria, viruses, and parasites. The word “prion” is derived from a combination of “protein” and “infection.”

CJD Pathology

CJD develops when a prion induces normally folded copies of proteins to conform to its misfolded structure, resulting in a chain reaction in which each new prion spreads its abnormal structure to other normal protein molecules. The misfolded proteins cannot be utilized by cells in the normal process of protein breakdown known as proteolysis; they then accumulate on the outside of the cells, eventually causing cell death. In the brain, the death of nerve cells results in vacuoles (small cavities) in the brain tissue resembling those of sponges, which can be seen on autopsy, giving the disease the spongiform description. CJD is grouped together with kuru, Gerstmann-Sträussler-Scheinker syndrome, fatal familial insomnia, and bovine spongiform encephalopathy (Mad Cow Disease) as a transmissible spongiform encephalopathy (TSE). TSEs are contagious (transmissible) and cause a sponge-like series of holes in the brain.

CJD is classified into several subtypes:

- **Sporadic:** Sporadic CJD occurs randomly within the general population and accounts for about 85% of cases. There is no recognizable pattern of transmission or set of risk factors in sporadic CJD.
- **Familial CJD (fCJD):** Familial CJD is caused by a mutation in the *PRNP* gene, which codes for the normal protein that is eventually converted to a prion, or PrPC. The mutated gene codes for the disease-causing misfolded protein, or PrPSc. The Sc in the name of the misfolded protein is derived from scrapie, a disease of sheep that is also a TSE. Familial CJD accounts for 10% to 15% of cases of CJD.

In this axial view through the brain, the folded cerebrum is seen forming two hemispheres. At lower center are two red areas of the thalamus diseased with CJD, which destroys nerve cells and causes brain tissue to become spongy. Symptoms include dementia, muscle contractions, and sometimes death. (Simon Fraser/Royal Victoria Infirmary, Newcastle Upon Tyne/Science Source)

- **Iatrogenic, or hospital-acquired, CJD:** Iatrogenic CJD is a form of the disease caused by contaminated surgical instruments, blood transfusions, human-derived growth hormone, or the use of transplanted tissue taken from the dura mater of an infected patient. About 250 cases of iatrogenic CJD were reported before strict sterilization protocols were made mandatory for the reuse of surgical instruments or the use of human-derived biological materials. There have been no cases of iatrogenic CJD reported since 1976.
- **Variant CJD (vCJD):** Variant CJD is another acquired form of CJD that develops when a person eats beef from a cow infected with bovine spongiform encephalopathy. The number of cases of vCJD peaked in 2000 and declined to about two cases per year by 2008. There have been about 229 cases of vCJD reported worldwide since 1996.

Genetic Susceptibility

Familial CJD is the only form of the disease that has a known genetic profile. It is caused by a mutation in the

PRNP gene on the short arm of chromosome 20 at 20p13. About 30 different mutations of the *PRNP* gene have been identified as causing fCJD. Some of these mutations replace single amino acids in the normal prion protein (PrPC), while other mutations add extra amino acids or remove portions of the normal protein, resulting in an unusually short form of it. These changes in the structure of the normal protein result in the disease-causing form PrPSc. This abnormal form binds to the normal PrPC, changing it into PrPSc. The abnormal PrPSc builds up in the tissues of the brain, because it cannot be broken down in the normal process of proteolysis. The clumps of PrPSc eventually destroy the neurons (nerve cells), producing the small vacuoles that give the diseased brain tissue a sponge-like appearance.

Familial CJD is transmitted in an autosomal dominant pattern, which means that only one copy of the mutated *PRNP* gene is necessary for the disease to appear in a patient.

Researchers have discovered that a person's risk of developing fCJD is influenced by a mutation in the *PRNP* gene at position 129 in the normal PrPC protein. People who inherit the same mutation from both parents at that spot are more likely to develop fCJD. In addition, they will usually develop symptoms of CJD at an earlier age and have a more rapid progression of the disease.

Epidemiology

All forms of CJD are very rare, affecting about one person per million. There are about 300 cases reported each year in the United States; of these, between 30 and 45 cases are fCJD.

Sporadic and familial CJD (sometimes grouped together as classic CJD) are almost entirely diseases of middle-aged or older adults. The average age at the time of symptom onset is 60. Persons with the familial form of CJD may develop symptoms as early as age 40. Males and females are equally affected. CJD occurs at the same rate worldwide in all races and ethnic groups.

vCJD affects younger adults, with an average age of 25 at the time of symptom onset. As with classic CJD, males and females are equally affected. Variant CJD has become increasingly rare since preventive measures related to the feeding and slaughter of cattle were introduced in the 1990s.

Signs and Symptoms

The signs and symptoms of classic CJD typically begin with dementia, a condition characterized by the loss

of not only memory but also judgment, reasoning ability, and the ability to carry out activities of daily life (ADLs). In contrast to such other dementing disorders as Alzheimer's disease, frontotemporal dementia, Lewy body disease, and others, the dementia associated with CJD progresses very rapidly; family members of patients with CJD often say that they can see the patient's mental functions decline from one day to the next. Other common symptoms of CJD include difficulties with speech or swallowing, visual problems, personality changes, insomnia, or depression. Some patients also have auditory or visual hallucinations and may go completely blind.

Another major symptom of CJD is myoclonus, which is the involuntary twitching or jerking of muscles or muscle groups. Fairly quickly in the course of the disease, the patient will usually have problems with walking and muscular coordination (ataxia), and they may become completely bedridden. Other neuromuscular symptoms of CJD include athetosis (slow, involuntary writhing movements of the hands, arms, or feet) and akinetic mutism, a condition in which the patient can neither move nor speak. Deterioration of the breathing muscles makes patients with CJD susceptible to pneumonia, which often hastens their death.

KEY TERMS

Akinetic mutism—A medical condition in which the patient is unable to move (akinetik) or speak (mutism).

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Athetosis—A condition marked by slow, writhing, involuntary muscle movements.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a non-sex chromosome is necessary for a disease or inherited trait to develop in an individual.

Dementia—A condition of deteriorated mental ability characterized by a marked decline of intellect and often by emotional apathy.

Dura mater—A thick membrane that is the outermost of the three layers of tissue (meninges) covering the brain and spinal cord. Tissue from this membrane has been used for transplantation in cases of head trauma but is now considered a risk factor for iatrogenic CJD.

Encephalopathy—The medical term for any global dysfunction of the brain. It is not a single disease but rather a syndrome that has many different causes and prognoses.

Iatrogenic—Referring to a symptom or disorder caused inadvertently by a medical intervention or diagnostic procedure.

Kuru—An incurable neurodegenerative disease that is classified as a transmissible spongiform encephalopathy. It is transmitted among humans by cannibalism.

Myoclonus—Twitching or spasms of a muscle or an interrelated group of muscles.

Polymorphism—A change in the base pair sequence of DNA that may or may not be associated with a disease.

Prion—A protein that can fold in several different and distinctive ways, one of which can be transmitted to other proteins.

Proteolysis—The breakdown of proteins into smaller units, usually polypeptides or amino acids.

Scrapie—A fatal disease of sheep and goats that is classified as a transmissible spongiform encephalopathy. Although scrapie is caused by a prion, it is not transmissible to humans.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

Vacuole—A small cavity found within organic tissue.

Diagnosis

The diagnosis of CJD is complicated by the fact that the condition is so rare that most doctors will never see a case of it in their entire careers. In addition, the early symptoms of CJD are not unique to the disease and can be easily confused with the symptoms of Parkinson's disease, Huntington's disease, Alzheimer's disease, tertiary syphilis, or major depression (if the initial symptoms are personality changes). There is at present no blood or urine test that can be used to screen for CJD.

Because CJD is incurable and invariably fatal, doctors begin the diagnostic process by attempting to determine whether the patient has a disease that can be treated, such as encephalitis (inflammation of the brain), neurosyphilis, or meningitis. Common tests include an electroencephalogram (EEG), which is often valuable because CJD produces distinctive sharp brain wave patterns. A spinal tap may be done to rule out infections of the central nervous system. The patient's cerebrospinal fluid may also be tested for 14-3-3 protein, a regulatory molecule that is found in elevated amounts in the CSF

of patients with CJD. Imaging studies may include a CT scan and an MRI. CT scans are useful in ruling out stroke or a brain tumor as the cause of the patient's symptoms. MRIs in particular will reveal patterns of deterioration in the brain tissue that point to CJD.

The next step in diagnosis is to evaluate the patient's clinical symptoms together with the results of the various imaging and other tests. According to the Centers for Disease Control and Prevention (CDC), the following criteria are used to determine the possibility or probability of a diagnosis of CJD:

- **Probable:** The patient has rapidly progressing dementia plus at least two of four other signs (myoclonus, akinetic mutism, visual disorders or ataxia, or abnormal reflexes) plus a positive result on at least one test (EEG, MRI, CT, or 14-3-3 protein), combined with the absence of an alternative diagnosis.
- **Possible:** The patient has progressive dementia plus two of the four signs (myoclonus, akinetic mutism, visual disorders or ataxia, or abnormal reflexes) plus the absence of a positive result on any of the tests (EEG,

MRI, CT, or 14-3-3 protein). The patient has also had the illness less than two years and does not have an alternative diagnosis.

A definite diagnosis requires examination of a sample of the patient's brain tissue. Although such a sample can be taken while the patient is alive, there is a considerable risk of missing the portion of the brain that is directly affected by the disease and thus obtaining a false negative. In addition, the biopsy risks exposing the surgeon and other healthcare personnel to contaminated body fluids and tissue. In most cases, the definite diagnosis of CJD is obtained only at autopsy.

Criteria for a diagnosis of fCJD include a diagnosis of probable or possible CJD in the patient, plus a diagnosis of probable or possible CJD in a first-degree relative (parent, child, or sibling), plus detection of a mutation in the *PRNP* gene on molecular genetic testing. Genetic counseling should be offered to other family members when a patient is diagnosed with fCJD.

In 2014, an international team of researchers reported that they had developed a technique for detecting the form of the prion protein implicated in sporadic CJD in nasal brushings taken from living patients diagnosed with CJD. The method proved to be more accurate than analysis of samples of cerebrospinal fluid, and it may offer a minimally invasive laboratory test for detecting sporadic CJD. Also in 2014, another group of researchers reported that they had developed a urine test that appears to be effective in detecting very small amounts of the abnormal PrP^{Sc} protein in patients with variant CJD.

Treatment and Management

There is no specific treatment for CJD, as the disease is incurable. Care is supportive. The patient may be helped by antidepressants for depression or anxiety, or clonazepam or an anticonvulsant drug to relieve severe myoclonus. Quetiapine has been found to be helpful in treating hallucinations. In general, patients with classic CJD will require skilled nursing care as the disease progresses, and they may prefer referral to a hospice for end-of-life care.

Although CJD is defined as transmissible, it is not contagious in the usual sense. People cannot contract CJD from touching or holding their loved one; it is not necessary to quarantine or isolate patients diagnosed with CJD or to restrict visits from friends and family members. Healthcare workers should, however, avoid exposure to cerebrospinal fluid and brain tissue from CJD patients.

Prognosis

The prognosis of all forms of CJD is uniformly grim, as there is no cure for the disease right now. The time

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever cared for a patient who turned out to have CJD?
- Do you think a cure will be developed someday for this disease?
- What advice would you give to a family with a member with possible or probable CJD?
- Would you recommend genetic testing to such a family?

from symptom onset to death ranges from a few months to five years.

Methods to Characterize the Misfolded Protein and Potential Treatments

Scientists have come a long way in characterizing the misfolding of mutant PRPC protein. With advanced imaging techniques, they have been able to locate the origin of misfolding on the protein and view the changes in shape as the protein misfolds. Scientists have also generated antibodies that bind to the location that initiates misfolding of the protein and prevent misfolding due to mutations. This work has pointed to an avenue of research around preventing misfolding.

Live human brain tissue may help screen potential treatments for CJD. Human cerebral organoids are small balls of human brain cells whose organization, structure, and electrical signaling mimic human brain tissue. Because studies in mice have failed to identify effective treatment in patients, human cerebral organoids are necessary to study potential treatments for CJD. Skin cells from patients are genetically engineered and manipulated to become brain cells for use in organoid research on CJD transmissibility and its inhibition.

Cri du chat syndrome

Definition

Cri du chat syndrome occurs when a piece of chromosomal material is missing from a particular region on chromosome 5. Individuals with this syndrome have unusual facial features, poor muscle tone (hypotonia), small head size (microcephaly), and intellectual disability. A classic feature of the syndrome is the cat-like cry made by infants with this disorder.

Description

Dr. Jerome Lejeune first described cri du chat syndrome in 1963. The syndrome is named for the cat-like cry made by infants with this genetic disorder. *Cri du chat* means "cry of the cat" in French. This unusual

cry is caused by abnormal development of the larynx (the organ in the throat responsible for voice production). Cri du chat syndrome is also called 5p minus syndrome because it is caused by a deletion, or removal, of genetic material from chromosome 5. The deletion that causes cri du chat syndrome occurs on the short or "p" arm of chromosome 5. This deleted genetic material is vital for normal development. Absence of this material results in the features associated with cri du chat syndrome.

A high-pitched mewing cry during infancy is a classic feature of cri du chat. Infants with cri du chat typically have low birth weight, slow growth, a small head (microcephaly), and poor muscle tone (hypotonia). They also may have congenital heart defects. Individuals with cri du chat syndrome have language difficulties, delayed motor skill development, and intellectual disability. Behavioral problems may also develop as the child matures.

Genetic profile

Cri du chat is the result of a chromosome abnormality. Human beings have 46 chromosomes in the cells of their body. Chromosomes contain genes, which regulate the function and development of the body. An individual's chromosomes are inherited from their parents, 23 chromosomes from the egg and 23 chromosomes from the sperm. The 46 chromosomes in the human body are divided into pairs based on their physical characteristics. Chromosomes can only be seen when viewed under a microscope.

Most chromosomes have a constriction near the center called the centromere. The centromere separates the chromosome into long and short arms. The short arm of a chromosome is called the "p arm." The long arm of a chromosome is called the "q arm."

Individuals usually have two copies of chromosome 5. Cri du chat is caused when the end of the short arm of the chromosome is deleted, or erased, from the "p" arm of one chromosome 5. The piece of chromosomal material deleted contains many genes necessary for normal development. One gene specifically known to be affected by this deletion is the *CTNND2* gene, which codes for a protein known as delta-catenin. Since delta-catenin is essential in the nervous system and muscular system, a deletion of this gene results in abnormal structure and function of the brain, nerves, and muscles of the human body. When these genes are missing, the larynx, brain, and other parts of the body do not develop as expected. This is what causes the symptoms associated with cri du chat.

In 90% of patients with cri du chat syndrome, the deletion is sporadic. This means that it happens randomly

and is not hereditary. If a child has cri du chat due to a sporadic deletion, the chance the parents could have another child with cri du chat is 1%. In approximately 10% of patients with cri du chat, there is a hereditary chromosomal rearrangement that causes the deletion. If a parent has this rearrangement, the risk of having another child with cri du chat is greater than 1%.

Demographics

It has been estimated that cri du chat syndrome occurs in 1 of every 50,000 live births. According to the 5p Minus Society, approximately 50–60 children are born with cri du chat syndrome in the United States each year. It can occur in all races and in both sexes.

Signs and symptoms

An abnormal larynx causes the unusual cat-like cry made by infants that is a hallmark feature of the syndrome. As children with cri du chat get older, the cat-like cry becomes less noticeable. This can make the diagnosis more difficult in older patients. In addition to the cat-like cry, individuals with cri du chat also have unusual facial features. These facial differences can be very subtle or more obvious. Microcephaly (small head size) is common. During infancy, many patients with cri du chat do not gain weight or grow normally. Approximately 30% of infants with cri du chat have a congenital heart defect. Hypotonia (poor muscle tone) is also common, leading to problems with eating, and slowing normal development. Intellectual disability and psychomotor retardation is present in all patients with cri du chat, but the degree of intellectual disability and physical retardation varies between patients.

Diagnosis

During infancy the diagnosis of cri du chat syndrome is strongly suspected if the characteristic cat-like cry is heard. If a child has this unusual cry or other features seen in cri du chat syndrome, chromosome testing should be performed. Chromosome analysis provides the definitive diagnosis of cri du chat syndrome and can be performed from a blood test. Chromosome analysis, also called karyotyping, involves staining the chromosomes and examining them under a microscope. In some cases, the deletion of material from chromosome 5 can be easily seen. In other cases, further testing must be performed. FISH (fluorescence in-situ hybridization) is a special technique that detects very small deletions. The majority of the deletions that

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Centromere—The constricted region of a chromosome. It performs certain functions during cell division.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted through either the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Congenital—Refers to a disorder that is present at birth.

Deletion—The loss of genetic material that is normally found in a chromosome. Often, the genetic material is missing due to an error in replication of an egg or sperm cell.

Hypotonia—Reduced or diminished muscle tone.

Karyotyping—A laboratory procedure in which chromosomes are separated from cells, stained, and arranged so that their structure can be studied under the microscope.

Microcephaly—An abnormally small head.

cause cri du chat syndrome can be identified using the FISH technique.

Cri du chat syndrome can be detected before birth if the mother undergoes amniocentesis or chorionic villus sampling (CVS). This testing would only be recommended if the mother or father is known to have a chromosome rearrangement or if they already have a child with cri du chat syndrome. Other high-accuracy

QUESTIONS TO ASK YOUR DOCTOR

- How did cri du chat syndrome get its name, and what relevance does it have today?
- Can you explain the genetic basis for this disorder?
- What are the most common health risks faced by an infant born with cri du chat syndrome?
- Are there support groups available for parents of children born with cri du chat syndrome?
- How much support and attention will my child need for activities of daily life?
- Is there testing that can be done prior to giving birth to our next child to know whether or not he or she will have a genetic disorder as well?

prenatal genetic screening for cri du chat syndrome includes single-nucleotide polymorphism (SNP)-based microdeletion testing and noninvasive prenatal genetic testing (NIGT). Both are noninvasive tests with high accuracy for detecting a deletion in genes such as *CTNND2* associated with cri du chat syndrome. All genetic testing should be done in conjunction with genetic counseling for making informed decisions if genetic testing is positive for any disorder.

Diagnostic imaging can also be helpful for diagnosing an infant with cri du chat syndrome. On MRI, hypoplasia of the brainstem, pons, and cerebellum is largely associated with prenatal congenital disorders like cri du chat syndrome.

Treatment and management

Currently, there is no cure for cri du chat syndrome. Treatment consists of supportive care and developmental therapy.

Prognosis

Individuals with cri du chat have a 10% mortality during infancy due to complications associated with congenital heart defects, hypotonia, and feeding difficulties. Once these problems are controlled, most individuals with cri du chat syndrome have a normal lifespan. The degree of intellectual disability can be severe. However, a recent study suggested that the severity is somewhat affected by the amount of therapy received.

CRISPR/Cas

Definition

CRISPR/Cas is a tool that is used by researchers to examine and change DNA. It is part of the immune system of bacteria and some other micro-organisms. Researchers are exploring its use for diagnosing and treating diseases and for agricultural applications. CRISPR/Cas is often shortened to CRISPR, pronounced "crisper."

Diagram of the process that occurs in CRISPR-Cas9 gene editing. A protein (purple) is used in genome engineering to cut DNA (deoxyribonucleic acid). It uses a guide RNA (ribonucleic acid) sequence (yellow) to cut DNA (orange and blue) at a complementary site. The cut area of DNA is also shown in yellow. The process of silencing a gene or inserting a fragment of donor DNA (purple) is shown at center, with examples of genetically modified organisms at bottom. (Jose Antonio Penas/Science Source)

Description

CRISPR and Cas are part of the immune system of micro-organisms like bacteria. CRISPR stands for clustered, regularly interspaced, short palindromic repeats. It is made up of segments of repeating DNA sequences and short segments of spacer DNA (spacers). The spacers are bits of DNA taken from viruses that have previously infected the bacteria. These spacers help bacteria to recognize and fight off future infections. Cas is a CRISPR-associated protein. It is like a pair of molecular scissors that can cut DNA. When the virus attacks the bacteria again, the CRISPR DNA creates RNA, which contains the viral sequence. This RNA then guides the Cas to a spot in the virus that has a complementary DNA sequence. Cas then cuts the viral DNA in this spot and destroys it. This helps to protect bacteria from other organisms like viruses.

CRISPR repeats were first identified in *E. coli* bacteria in the 1980s, but major CRISPR/CAD development did not begin until 2005. By 2012, researchers were able to make CRISPR RNAs that could guide a Cas protein to target any DNA sequence. They were able to apply it to several species, including yeast, fish, flies, nematodes, plants, mice, monkeys, and humans. Since then, researchers have rushed to obtain patents on this technology. As of 2020, the Broad Institute appears to be winning this battle in the United States as it relates to animal and plant cells.

There are two different classes of CRISPR-Cas systems (I and II), which are subdivided into six types (I, II, III, IV, V, VI). The different classes and types are based on the structure and function of the Cas protein involved. The most commonly used systems by researchers are type II (Cas9), Type V (Cas12a) and Type VI (Cas13). CrisprGE (<http://crdd.osdd.net/servers/crisprge>) is a central online data base with a catalogue of more than 200 unique published CRISPR genes from more than 30 different model/animal systems. The website provides free tools for researchers who are interested in working with CRISPR/Cas systems.

Applications for CRISPR-Cas

There are many potential applications for CRISPR-Cas, such as diagnosing and treating genetic conditions, combating infectious diseases like COVID-19 and HIV, and genetically modifying crops. The two major areas where CRISPR-Cas has been used are gene editing and diagnosing disease.

CRISPR-Cas gene editing

CRISPR-Cas can be used to change an organism's DNA by making a cut in the DNA at a specific location and tricking the body's DNA repair mechanism to make

KEY TERMS

Endonucleases—Enzymes that recognize short pieces of DNA (often palindromic) and cleave either within or near the recognized sequence.

Gene editing—A process that involves changing an organism's DNA by removing, adding, or changing it.

Guide RNA (gRNA)—A combined tracer RNA and spacer RNA (pre-crRNA) that, when used in conjunction with a Cas9 nuclease (crRNA), can target and cut specific DNA sequences.

Leader sequence/leader RNA—Also known as the 5' untranslated region (5' UTR), the section of mRNA found immediately before the initiation codon for translation of a transcript.

Locus—The position occupied by a gene on a chromosome.

Operon—A functional unit of genomic DNA containing several genes under the control of one promoter.

Protospacer—A regularly sized piece of phage DNA that has been excised and incorporated into the CRISPR array.

Protospacer-adjacent motifs (PAMs)—Highly conserved short DNA sequences (2bp–5bp) that are necessary for the excision of adjacent protospacers.

the desired change. This technique has been used extensively in food production and agriculture. For example, CRISPR/Cas can be used in yogurt production to help prevent the good bacteria in yogurt from being destroyed by viruses. CRISPR/Cas has also been used to change the DNA of certain crops to improve their nutrition, drought tolerance, and pest resistance.

A significant amount of research is being done to use CRISPR-Cas to treat genetic diseases such as sickle cell disease and cystic fibrosis and infectious diseases such as COVID-19 and HIV. CRISPR/Cas is currently only being used on humans in clinical trials. It can be used to treat genetic conditions both outside the body (ex vivo) and inside the body (in vivo). For example, CRISPR/Cas was used to treat sickle cell disease ex vivo. Sickle cell disease is a genetic disease that causes abnormal red blood cells that cannot properly carry oxygen throughout the body. A woman with sickle cell disease was successfully treated by removing cells from her bone marrow, using CRISPR/Cas to edit the DNA of these cells, and infusing the repaired cells back into

QUESTIONS TO ASK YOUR DOCTOR

- Are there currently clinical trials for CRISPR/Cas-based therapies that are pertinent to my illness/disease?
- What are the risks associated with gene-editing therapies, and are there other alternatives?
- How does CRISPR/Cas gene editing work?
- What prognosis can you offer with this type of treatment?

her body. Another clinical trial is testing CRISPR/Cas in vivo to treat a genetic cause of blindness called Leber's congenital amaurosis. The CRISPR/Cas components are injected directly into the eye to repair the DNA variation causing the blindness. Researchers are also investigating using CRISPR/Cas to treat COVID-19 by targeting and cutting the viral DNA. They are also testing using CRISPR/Cas for treating other diseases such as hepatitis C, cancer, muscular degenerative diseases, and cystic fibrosis.

Diagnosing disease using CRISPR-Cas

CRISPR/Cas can be used for diagnosing infectious and genetic diseases. For example, a custom CRISPR/Cas can be created that will recognize and make a cut only if a specific genetic sequence associated with the COVID-19 virus is present. In one type of test, called SHERLOCK, the virus is present if a line appears on a special paper strip that is dipped into the sample.

CRISPR/Cas can also be used to diagnose mutations in DNA that can cause genetic diseases. For example, researchers in California have created a device with a CRISPR-Chip, which identifies specific mutations. The researchers were able to use the device to identify genetic mutations associated with Duchenne muscular dystrophy.

Limitations and ethical issues

Although CRISPR/Cas is powerful, it has a number of limitations:

1. It is hard to deliver CRISPR/Cas to cells in large numbers.
2. Not all cells that take in CRISPR/Cas are able to edit the DNA.
3. Sometimes CRISPR/Cas can cause unintended variations (mutations) in other parts of the DNA.

It is possible to change the DNA of eggs and sperm and early embryos using CRISPR/Cas. This technique is called germline editing. These types of changes will cause permanent changes in the individual and their offspring. Germline editing also allows CRISPR/Cas to be used to improve desirable traits rather than curing disease. It could also result in unintended changes to other parts of the DNA that could cause cancer, genetic disease, and other problems. Most scientists support a moratorium on using CRISPR/Cas for germline editing until more research is done and global ethical guidelines are developed. Germline editing has been banned in many countries. One example of how this experimentation can go wrong occurred in 2018. Chinese scientists performed germline editing using CRISPR/Cas on twin girls to make them more resistant to HIV. Unfortunately, the gene variation introduced into these babies may also make them and future generations more susceptible to other infections, such as influenza. This germline editing using CRISPR/Cas may also have introduced other unintended mutations. This experiment received international condemnation and renewed calls for an international moratorium on germline editing. The scientists involved were sent to prison and fined as a result.

Crohn's disease

Definition

Crohn's disease is a common form of inflammatory bowel disease (IBS). It is an often serious condition that leads to inflammation and thickening of the walls of the bowel. In some cases, painful sores or ulcers of the digestive tract may develop. The most common features of Crohn's disease include chronic diarrhea, abdominal pain, decreased appetite, weight loss, fatigue, and fever.

Description

The inflammation of Crohn's disease primarily affects the large intestine and lower parts of the small intestine. The chronic swelling and thickening of intestinal lining lead to ulcers and open sores that cause the symptoms of diarrhea, abdominal cramping, loss of appetite, and weight loss experienced by those with Crohn's.

In addition to intestinal discomfort and symptoms, individuals with Crohn's disease may also experience persistent intestinal bleeding that may lead to anemia, a reduced number of red blood cells in the body; medical conditions that affect other parts of the body such as the eyes, joints, and skin; and intestinal blockage. A serious complication of this disease, intestinal blockage, may become life-threatening.

Genetic profile

Crohn's disease is caused by abnormalities of chromosome 5 and 10 and mutations in the *ATG16L1*, *IL23R*, *IRGM*, and *NOD2* genes. These chromosomal and genetic changes are associated with an increased risk of developing Crohn's disease.

The causes of Crohn's disease are complex and varied, involving behavioral, environmental, and genetic factors. Cigarette smoking is believed to increase the risk of developing the disease and may increase the number of flare-ups in individuals who have been diagnosed. Changes in an individual's immune system and the presence of certain bacteria in the digestive tract may also contribute to the development of Crohn's disease.

Specific genetic factors that lead to Crohn's disease include mutations in the *ATG16L1*, *IL23R*, *IRGM*, and *NOD2* genes. Each of these genes is significant in the formation of proteins important in developing and maintaining a healthy immune system. Mutations in any of these genes may cause the cells of the intestinal system to respond abnormally to bacteria and may lead to inflammation and the symptoms of Crohn's disease.

Abnormalities in specific regions of chromosomes 5 and 10 are associated with an increased risk of developing Crohn's disease. Specifically, abnormalities of the IBD5 locus of chromosome 5 have been found in individuals with Crohn's disease. Additionally, regions of chromosome 5 and 10 have large areas known as "gene deserts" that do not contain individual genes. Researchers believe that these regions may be important in regulating nearby genes, and suspect that these areas may be important in determining the genetic causes of Crohn's disease.

It is likely that there is an inheritance pattern for Crohn's disease because the disease does appear to run in families; however, the exact mechanism of inheritance has not been discovered.

Demographics

More than 780,000 Americans are affected by Crohn's disease. The condition is more common in Western Europe and North America, and occurs more frequently in whites and descendants of Ashkenazi Jews.

Signs and symptoms

The most common symptoms of Crohn's disease are chronic diarrhea, abdominal pain, decreased appetite, weight loss, fatigue, and fever. In addition to these symptoms, individuals with Crohn's may also have chronic anemia due to internal bleeding caused by open sores along the intestinal lining. This disease may also cause inflammation throughout the body. That systemic inflammation may cause abnormalities of the eyes, skin, and joints. A serious complication of Crohn's disease is intestinal blockage. Layers of thickened scar tissue may accumulate in the large and/or small intestine. This thickened tissue may completely block the bowel and prevent waste from exiting the body. If this occurs, immediate medical treatment is required.

Another condition caused by Crohn's disease is the formation of a fistula. A fistula is an abnormal opening in the bowel wall that connects to other tissue or another organ. These openings may connect to other abdominal organs such as the bladder or the vagina, and must be surgically repaired to prevent solid waste from entering these organs.

Diagnosis

Before a diagnosis of Crohn's disease is made, other causes for symptoms must be ruled out. In order to make an accurate diagnosis, doctors will record a complete medical and family history, and will compile a list of the patient's symptoms. Once other conditions and diseases are excluded, medical tests will be performed to diagnose Crohn's.

Laboratory tests that may be performed include the following:

- **Complete blood count (CBC)**—A blood test that counts blood cells and can determine if anemia or infection is present.

- **Fecal occult blood test**—A test in which a stool sample is examined to look for blood cells.

Imaging and scoping tests that may be used to diagnose Crohn's disease include the following:

- **Endoscopy**—A thin, flexible, lighted tube with an attached camera is inserted through the mouth into the upper portion of the digestive tract. Doctors are able to view the upper digestive tract for signs of sores or other symptoms of Crohn's disease.
- **Colonoscopy**—A thin, flexible, lighted tube with an attached camera is inserted into the rectum and guided through the colon. This test provides images of the entire colon. The doctor may also take small samples of tissue (biopsy) for testing to help confirm a diagnosis. The presence of granulomas, clusters of inflammatory cells, in the colon will help confirm the diagnosis of Crohn's.
- **Flexible sigmoidoscopy**—A thin, flexible, lighted tube is inserted in the colon and moved to the sigmoid, the section of the colon closest to the rectum.

- Computerized tomography (CT) scan—An imaging test that uses x-rays and computers to provide detailed images of the entire bowel as well as tissues outside the bowel.
- CT enterography—A specialized type of CT scan used to provide detailed images of the small intestine. This test has replaced barium x-ray tests in some circumstances.
- Magnetic resonance imaging (MRI)—An imaging test that uses a magnetic field and radio waves to create detailed images of organs and tissues. MRI is particularly useful for evaluating fistulae in the bowels.
- Capsule endoscopy—This test uses a small camera inside a capsule that is swallowed. Images from the camera are transmitted to a computer worn on the patient's waist. The images are then downloaded to a computer and examined by a doctor for signs of Crohn's disease. The camera is shed painlessly from the body when stool is passed.
- Double-balloon endoscopy—For this test, a longer scope is used to look farther into the small bowel where standard endoscopes do not reach. This technique is useful to help confirm a diagnosis when capsule endoscopy shows abnormalities.
- Small bowel imaging—This test looks at the part of the small bowel that can't be seen by colonoscopy. The patient swallows a liquid containing barium; and x-ray, CT, or MRI images of the small intestine are taken. The images are used to confirm diagnosis.

Treatment and management

There is currently no cure for Crohn's disease. Treatment is designed to lessen the severity of the symptoms and increase the comfort of the individual. Effective treatment will decrease symptoms, improve long-term prognosis, and possibly lead to remission.

There is no one general treatment for all people with Crohn's disease. Treatment is individualized and tailored to meet the needs of each patient. The primary treatment involves drug therapy and medication with the goal of reducing the inflammation that is the main cause of symptoms.

Categories of drug therapy for Crohn's disease include the following:

- Anti-inflammatory drugs—Anti-inflammatory drugs are often the first step in the treatment of inflammatory bowel disease. Some anti-inflammatory drugs used to treat Crohn's disease include oral 5-aminosalicylates, sulfasalazine (Azulfidine), and mesalamine (Asacol, Delzicol, Pentasa, Lialda, Apriso). These drugs, especially sulfasalazine, have numerous side effects, including nausea,

diarrhea, vomiting, heartburn, and headache and are used less frequently than they once were.

- Corticosteroids—These medications, such as prednisone, help reduce inflammation in the entire body. They have many side effects, including facial swelling, excessive facial hair growth (in men and women), night sweats, insomnia, and hyperactivity. More serious side effects include hypertension, diabetes, osteoporosis, bone fractures, cataracts, glaucoma, and an increased chance of infection. Budesonide (Entocort EC), a newer type of corticosteroid, appears to work better with fewer side effects. However, its effectiveness is limited to reducing inflammation in specific areas of the colon. Corticosteroids may not be used for long term treatment; however, they may lead to remission when they are combined with immune suppressor medications.

- **Immunomodulators**—There are two types of immunomodulator medications: immune system suppressors and immune system stimulants. Immune system suppressors lessen the effect of the body's natural defenses in an attempt to reduce inflammation. These medications may increase the risk of developing certain infections and cancers. Immune stimulant medications increase the body's natural defenses so that those defenses can help fight inflammation. Azathioprine, mercaptopurine, methotrexate, and levamisole are the most frequently prescribed immunomodulators. The BCG vaccine, a vaccine for tuberculosis, has been shown to be an effective treatment for Crohn's. A combination of these drugs, rather than a single drug, may work better for some people.

There are many side effects to immunomodulator treatment, such as nausea and vomiting. In the short term these medications may be associated with inflammation of internal organs such as the liver or pancreas and may affect the functioning of bone marrow. Side effects of long-term treatment, though rare, include an increased risk of significant infection and cancers such as lymphoma and skin cancer.

- **Tumor necrosis factor (TNF) inhibitors**—These drugs work by neutralizing an immune system protein known as tumor necrosis factor (TNF). They are prescribed to both adults and children who have moderate to severe symptoms of Crohn's disease to help reduce signs and symptoms. Examples of TNF inhibitors include infliximab (Remicade), adalimumab (Humira), and certolizumab pegol (Cimzia). TNF inhibitors may be prescribed soon after diagnosis, especially if there is a family history of serious complications from Crohn's disease or if a fistula is present. TNF inhibitors may be combined with other medications or be used when other medications have been ineffective. In some cases, TNF inhibitor therapy may lead to remission. Side effects of TNF inhibitors include an increased risk of developing serious infections and some cancers such as lymphoma and skin cancers.

Other medications that may be prescribed to treat Crohn's disease include the following:

- **Methotrexate (Rheumatrex)**—This drug, often used to treat cancer, psoriasis, and rheumatoid arthritis, may be prescribed to people with Crohn's disease for whom other medications have been ineffective. Short-term side effects include fatigue, nausea, diarrhea, and rarely, potentially life-threatening pneumonia. Long-term use may lead to bone marrow suppression, scarring of the liver, or cancer.
- **Cyclosporine (Gengraf, Neoral, Sandimmune) and tacrolimus (Astagraf XL, Hecoria)**—These are extremely powerful medications generally prescribed to patients

QUESTIONS TO ASK YOUR DOCTOR

- Is there another disease that could be causing my symptoms?
- What happens if I stop taking my medications?
- What over-the-counter drugs can I take?
- What type of diet should I eat?
- May I crush my medication to take it orally?
- What other lifestyle changes should I make?

with Crohn's-related fistulas and those for whom other medications have been ineffective. Not suitable for long-term use, cyclosporine may cause serious side effects including organ damage (specifically kidney and liver damage), seizures, and fatal infections.

- **Vedolizumab (Entyvio) and natalizumab (Tysabri)**—These drugs work by stopping immune cells called integrins from binding to other cells in the intestinal lining. They are used to fight inflammation in patients for whom other medications have been ineffective. Natalizumab is only approved for experimental treatment because it has been associated with a serious side effect, leukoencephalopathy, a progressive brain disease that may lead to permanent disability or death. Vedolizumab works similarly to natalizumab but appears not to have the same risks.
- **Ustekinumab (Stelara)**—Used to treat psoriasis, this drug has been found to reduce symptoms of Crohn's disease. It may be prescribed when other medical treatments fail.
- **Antibiotics**—Antibiotics are used to treat infection, inflammation, and fistulas associated with Crohn's disease. Some researchers suspect antibiotics help reduce harmful intestinal bacteria that may play a role in overstimulating the intestinal immune system and may lead to inflammation. Antibiotics may be prescribed in addition to other medications when infection is a concern.
- **Over-the-counter medications**—In addition to controlling inflammation, some medications may help relieve signs and symptoms of Crohn's disease. Always talk to a doctor before taking any over-the-counter medications; however, depending on the severity of Crohn's disease, the doctor may recommend one or more of the following:
- **Antidiarrheals** like psyllium powder (Metamucil), methylcellulose (Citrucel), or loperamide (Imodium)

- Pain relievers such as acetaminophen (Tylenol, others). Other common pain relievers such as ibuprofen (Advil, Motrin IB, others) and naproxen sodium (Aleve, Anaprox) are not recommended because they are likely to make symptoms worse and can make the disease worse as well
- Iron supplements to help alleviate decreased iron caused by intestinal bleeding
- Supplements such as vitamin B, calcium, and vitamin D to help decrease the increased risk of osteoporosis that people with Crohn's disease may face

Other treatment options that may decrease the symptoms of Crohn's disease include the following:

- Nutrition therapy—A special diet including enteral nutrition (tube feeding with a highly nutritious liquid diet) or parenteral nutrition (nutrients injected directly into a vein). Either of these options may give the bowel time to rest and heal, which may reduce inflammation in the short term. These therapies may also be used with immune system suppressors. Enteral and parenteral nutrition are typically used to help people become more stable and healthier before surgery, or when symptoms do not respond to other medications. A low-residue or low-fiber diet designed to reduce the size and number of stools may be prescribed to reduce the risk of intestinal blockage.
- Surgery—If other treatment options are not effective, surgery may be required to help decrease or eliminate symptoms of Crohn's disease. Up to half of all individuals with Crohn's disease will require at least one surgery. During surgery, the damaged portion of intestine is removed and the intestine is reconnected to healthy sections. Strictureplasty, which widens a too-narrow segment of the intestine, is common for patients with Crohn's disease. The benefits of surgery for Crohn's disease are usually temporary, and surgery is not a cure for Crohn's disease. The disease often recurs frequently near the reconnected tissue. Surgery is generally followed by drug therapy to reduce the risk of recurrence.

Prognosis

Most individuals with Crohn's disease will have a normal life expectancy. Rarely, complications from the disease may lead to early death. There is no cure for Crohn's disease; however, the symptoms may be managed through medication, diet modification, and sometimes surgery. A characteristic of the disease is symptom flare-ups. The symptoms may disappear for periods of time only to recur.

Individuals with Crohn's may be at a greater risk of developing colon cancer, and doctors often recommend colon cancer screening on a regular basis.

Other conditions that may occur more frequently in individuals with Crohn's disease include the following:

- anemia
- fistulas in the bladder, skin, or vagina
- intestinal infection
- intestinal blockage
- delayed growth and development in children
- difficulty maintaining healthy body weight
- joint swelling and pain
- nutritional deficiencies

Crouzon syndrome

Definition

Crouzon syndrome is a genetic condition that causes early closure of the bones in the skull. This event is called craniosynostosis and causes the skull to form abnormally.

Because of the craniosynostosis, individuals affected with Crouzon syndrome have characteristic facial features.

Description

Features of Crouzon syndrome include wide-set prominent eyes. Individuals with this syndrome may also have a condition called strabismus, which means that the eyes have difficulty focusing on objects. Other facial features may include an underdeveloped upper jaw, which causes tooth abnormalities. Individuals with Crouzon syndrome often have a beak-shaped nose and hearing loss. A skin condition called acanthosis nigricans occurs in approximately 5% of individuals with Crouzon syndrome. It is important to note that there is a wide range of severity in Crouzon syndrome. No two individuals with the condition will necessarily have all of the listed features.

Affected individuals often undergo several corrective surgeries, increasing the need for continual medical care throughout their lives. This can be very stressful and difficult for patients and their families. Additionally, since people with Crouzon syndrome have significant facial differences, it may be difficult for them (and their parents) to feel accepted by society. There may be psychological implications, ranging from feeling bad for “looking different” to parents who have trouble bonding with their child. The psychological impact may be less if there are others in the family with Crouzon syndrome. Having more than one family member with this syndrome may help those affected to feel less isolated and provide them with a stronger support system.

Genetic profile

Crouzon syndrome is caused by mutations in the *FGFR2* gene (on the long arm q of chromosome 10 at 10q25.3-q26) and the *FGFR3* gene (on the short arm p of chromosome 4 at 4p16.3). At least 40 different mutations in the *FGFR2* gene are known to cause Crouzon syndrome, which is inherited in an autosomal dominant manner. Affected individuals have one copy of a gene with the *FGFR* mutation as well as a normal copy of the *FGFR* gene, and thus have a 50% chance of passing the mutation on to each of their children, regardless of those children’s sex. About 75% of affected people have a family history of Crouzon syndrome—typically a parent with the condition. In the remaining 25% of people with Crouzon syndrome, the genetic mutation is new (*de novo*) in the affected individual and there is no family history of the disorder. One factor in the risk for these new mutations is advancing paternal age. However, with no family history of the condition, there is

KEY TERMS

Acanthosis nigricans—A skin condition characterized by darkly pigmented areas of velvety, wart-like growths. Acanthosis nigricans usually affects the skin of the armpits, neck, and groin.

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is necessary for a disease or inherited trait to develop in an individual.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted through either the mother’s vagina or abdominal wall, and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic disorders.

Coronal suture—The skull suture that lies behind the forehead area, across the head from the left side to the right side.

Craniosynostosis—Premature, delayed, or otherwise abnormal closure of the sutures of the skull.

FGFR2* and *FGFR3—The genes encoding fibroblast growth factor receptors 2 and 3; mutations in these genes can cause Crouzon syndrome.

Fibroblasts—Connective tissue cells.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as a disease, and that can be transmitted to offspring.

Otolaryngologist—A physician who specializes in the care of the ear, nose, and throat and their associated structures.

Strabismus—An improper muscle balance of the ocular muscles affecting binocular vision.

Suture—In anatomy, fibrous joints that hold the bones of the skull together.

no increased risk for Crouzon syndrome in the affected child’s siblings.

FGFR2 and *FGFR3* are responsible for the proper differentiation, growth, and movement of cells in the

body called fibroblasts. Fibroblasts are part of the bony structures of the body, including the skull, so problems with fibroblast growth and movement lead to skull/bone problems. About 95% of patients have an *FGFR2* mutation, and 5% have an *FGFR3* mutation. Almost all affected individuals who also have acanthosis nigricans appear to share a common *FGFR3* mutation.

Demographics

Crouzon syndrome occurs in about 1 per 25,000 live births. It affects all ethnic groups equally.

Signs and symptoms

The most common characteristic of Crouzon syndrome is bilateral (two-sided) coronal craniosynostosis. A cloverleaf skull may be present if the sagittal (long suture from the front to back of the head) and/or lambdoidal (short suture at the very back of the head) sutures are involved. This causes the skull shape to be taller than usual, often described as “tower-shaped.” The pattern looks like a cloverleaf because the skull is taller, and the sides of the skull and face bulge slightly from right to left. The eye orbits are always very shallow, causing the eyes to protrude significantly. Strabismus may be present, and eyes may be wide-set, making vision poor. Some individuals also have unexplained difficulties with vision. The nose can be narrow and beak-shaped, forcing people to breathe through their mouths.

The upper jaw may not be properly formed and can cause dentition problems, most commonly a missing tooth. The palate (upper ridge of the mouth) may be high and narrow, causing crowding of the existing teeth. Occasionally, clefting (improper closure) of the lip and palate occur. Mild to moderate conductive hearing loss (due to abnormal ear structure formation) occurs in some cases.

Intellectual development is typically within the normal range. Only rare cases of significant mental deficiency have been reported. Hydrocephalus, which is an accumulation of fluid in the brain and skull, occurs in about 30% of patients and may progress or worsen with time. It typically shows up as a general enlargement of the skull. Sometimes the fluid can put increased pressure on various structures in the brain, limiting their growth and development. Hydrocephalus may explain the few reported cases of Crouzon syndrome with learning problems. Occasionally, seizures occur with Crouzon syndrome.

Individuals with Crouzon syndrome may be shorter than normal height. This characteristic seems to affect females more than males.

Diagnosis

Historically, Crouzon syndrome has been diagnosed after careful physical examination and further studies. A diagnosis of Crouzon syndrome can be made by observing several of the following features. The abnormally shaped head is typically seen in newborns; sometimes it can be observed prenatally in an ultrasound examination. X-rays or physical examination of the skull can diagnose craniosynostosis. Once craniosynostosis is seen, it is important to determine whether it has occurred because of the abnormal formation of the cranial suture, possibly caused by an *FGFR* mutation. This is known as primary craniosynostosis and suggests Crouzon syndrome as a possibility. Craniosynostosis may also be caused by abnormal forces (secondary craniosynostosis) such as decreased brain growth or abnormal fetal head positioning. This can occur in the prenatal period, and in these cases, the abnormal head shape may correct itself with time. The next step in diagnosis is to determine the type of craniosynostosis. A cloverleaf skull makes Crouzon syndrome a possibility, but it is seen more commonly in other genetic craniosynostosis syndromes.

Some babies with Crouzon syndrome have breathing problems as newborns due to narrowed nasal passages. Protruding eyes are a hallmark feature for the condition and can be observed almost immediately after birth. The lack of abnormalities in the extremities (hands and feet) is also considered part of the diagnosis of Crouzon syndrome rather than another type of craniosynostosis.

Molecular (DNA-based) genetic testing is available for Crouzon and other *FGFR*-related syndromes. These tests are specific for Crouzon, distinguishing it from other craniosynostosis syndromes. A blood or other type of sample (such as fetal cells from amniotic fluid) from the affected individual is analyzed for *FGFR2* and *FGFR3* gene mutations. A negative result may indicate that the individual has a different condition or a previously unidentified mutation in an *FGFR* gene. Once a specific mutation is found in a family, other family members can be tested. Patients with features of Crouzon syndrome and acanthosis nigricans can be tested for the common *FGFR3* mutation.

Prenatal testing is available for both *FGFR2* and *FGFR3* mutations from samples obtained via amniocentesis or chorionic villus sampling (CVS). This is only offered when a parent has a *known* mutation. However, identifying a mutation by prenatal testing does not define the extent of the symptoms. The severity of Crouzon syndrome can only be determined after birth. A prenatal ultrasound can sometimes make a possible diagnosis of a syndrome involving craniosynostosis, but it is not as accurate as direct DNA testing. A cloverleaf skull seen on a prenatal ultrasound usually

QUESTIONS TO ASK YOUR DOCTOR

- How is Crouzon syndrome diagnosed in an infant?

- Should family members have genetic testing?

implies a more severe outcome for the baby than with other types of craniosynostosis.

Treatment and management

Treatment of Crouzon syndrome often involves the coordinated efforts of several medical specialists in a team setting. The specialists may include a pediatrician, plastic surgeon, neurosurgeon, geneticist, genetic counselor, dentist, social worker, audiologist, speech pathologist, psychologist, and otolaryngologist.

Craniosynostosis is typically repaired through a series of operations. There is a major surgery performed as early as the first three months of life, followed by several others that may extend over the lifespan. Each series of operations is tailored to the individual, but it is rare for the corrections to be perfect. Because the skull is continually growing in the early part of life, timing of these surgeries is critical for proper brain formation and better results. Surgeries after the skull has stopped growing rarely yield good results. Surgeries performed before various portions of the facial region have stopped growing also have a poor prognosis and will require additional follow-up procedures.

For individuals with hydrocephalus, sometimes a shunt, or tube, needs to be placed to allow the fluid to drain from the affected area(s) of the brain.

For babies with respiratory distress, oxygen and ventilation may be provided. Occasionally, a tracheostomy (opening in the windpipe) is created to help the baby breathe.

Because their eyes protrude so significantly, people with Crouzon syndrome sometimes have trouble closing their eyes. Surgical eye closure may be necessary; this allows the eye and its various structures (such as the cornea) to remain protected.

Occasionally, surgeries to correct structural ear abnormalities (resulting in hearing loss) are necessary.

Prognosis

The most problematic complication in Crouzon syndrome is the craniosynostosis. Prognosis primarily depends upon the severity and extent of this skull abnormality. Consequently, the success of corrective surgeries often determines prognosis.

Crouzonodermoskeletal syndrome

Definition

Crouzonodermoskeletal syndrome is a genetic disorder that is similar to Crouzon syndrome but with a skin condition called acanthosis nigricans. It is sometimes referred to as Crouzon syndrome with acanthosis

nigricans. A primary symptom of both Crouzonodermoskeletal and Crouzon syndromes is the premature fusion of the bones in the skull during development. Crouzonodermoskeletal syndrome results from a mutation in only one of the *FGFR* genes that are involved in Crouzon syndrome.

Description

Crouzonodermoskeletal syndrome is a genetic disorder that results from a mutation in a gene that carries the instructions for making fibroblast growth factor receptor 3 (*FGFR3*), a protein that participates in the development of cells, particularly those in bones and in the brain. Individuals need only inherit the altered gene from one parent to develop this disorder. More often than not, however, the genetic mutation arises spontaneously, so affected individuals have no family history of the disorder.

Premature fusion of certain skull bones (craniosynostosis) during development causes the skull to have an abnormal, noticeably asymmetric shape. Acanthosis nigricans is a skin condition distinguished by velvety, dark patches that may appear on the neck, under the arms, at finger joints, in the groin, or in other places where the skin is folded or creased. The color of the patches may vary from light brown to purplish brown to black.

Genetic profile

Located on chromosome 4, the *FGFR3* gene carries the blueprint for making fibroblast growth factor receptor 3, one of several fibroblast growth factor receptors in the body. These receptors bind with fibroblast growth factors, which are proteins that are important for functions such as the creation of new blood vessels (angiogenesis), wound healing, and growth of embryos. *FGFR3* participates in the development and maintenance of bone and brain tissue. In particular, it is believed to control the transformation of cartilage to bone during growth. Cartilage makes up much of the skeletons of embryos and infants, and gradually changes to bone with growth and development. Although the exact mechanism is unknown, mutations in the *FGFR3* gene cause the bones in the skull to fuse prematurely. Normally, the bones in a baby's skull fuse slowly over about the first two years of life, after which the baby's head has assumed its adult shape. In Crouzonodermoskeletal syndrome, the bones join together earlier than they should, resulting in the characteristic head and facial features of this disorder.

The *FGFR3* mutations that cause this disorder result in the substitution of single amino acids, the building blocks of proteins, in the *FGFR3* protein. In particular, the amino acid alanine is replaced with the amino acid glutamate. There are other *FGFR3* mutations that are

Cartilage—A tough elastic tissue that is a building block for bone.

Cementoma—A type of noncancerous tumor that contains a bony substance known as cementum.

Craniosynostosis—Premature, delayed, or otherwise abnormal closure of the sutures of the skull.

Crouzon syndrome—A genetic disorder that is similar to Crouzonodermoskeletal syndrome but without acanthosis nigricans.

Divergent strabismus—Eyes that point in different directions due to imbalanced eye muscles.

Fibroblast growth factors—Proteins that are important in such functions as the growth of new blood vessels (angiogenesis), wound healing, and embryonic growth.

Sleep apnea—A potentially life-threatening condition in which the individual has episodes during sleep in which breathing temporarily stops.

associated with other bone-growth disorders, including the following:

- achondroplasia
- hypochondroplasia
- Muenke syndrome
- thanatophoric dysplasia

Crouzonodermoskeletal syndrome is an autosomal dominant disorder, which means that an individual need have only one mutated *FGFR3* gene to develop the condition. The mutation may be inherited from a parent who has signs and symptoms of Crouzonodermoskeletal syndrome. Each of this parent's children has a 50% chance of inheriting the mutated gene. If both parents have the mutation, each of their children has a 75% chance of inheriting it. As noted, however, most cases of Crouzonodermoskeletal syndrome arise from spontaneous mutations, so the patient has no family history of the disorder. It is unknown why these spontaneous mutations occur.

QUESTIONS TO ASK YOUR DOCTOR

- Should my child have genetic testing for a mutation that causes Crouzonodermoskeletal syndrome?
- What are the risks of cranial surgery, and what surgical options are available?
- What improvements should be expected from cranial surgery?
- What is involved in the surgery to correct protruding eyes, and is there a possibility that my child's vision will be affected?
- Will lower jaw surgery affect speech?

Demographics

Crouzonodermoskeletal syndrome is an extremely rare genetic disorder that affects an estimated one in a million people. The incidence does not vary with sex, ethnicity, or geographic area.

Signs and symptoms

The appearance of various symptoms and their severity differ from one individual to the next. Crouzonodermoskeletal syndrome typically does not affect intelligence. Common symptoms include the following:

- premature joining of skull bones
- shallow eye sockets with eyes that are far apart and often protruding, sometimes in a very pronounced manner
- eyes that point in different directions (divergent strabismus)
- a small nose and upper jaw and comparatively large lower jaw
- flattened nasal passages, often externally evident as a so-called beaked nose
- sleep apnea (momentary halts in breathing during sleep)
- flattened temples
- acanthosis nigricans
- noncancerous tumors (cementomas) in the jaw that develop during young adulthood

Diagnosis

Crouzonodermoskeletal syndrome is sometimes evident in an ultrasound performed during pregnancy, but this is not always the case. Often, the skull abnormalities are only noted at or shortly after birth.

Examination

After obtaining a family history of the patient, including potential inherited disorders, the doctor will typically perform a neurological examination to determine the extent of movement problems.

Tests

Genetic tests are available for *FGFR3* gene mutations.

Procedures

The doctor may order magnetic resonance imaging (MRI). While MRI cannot positively diagnose Crouzonodermoskeletal syndrome, it can help the doctor eliminate other disorders as possibilities.

Treatment and management

The premature fusion of skull bones can result in too little room for the brain to grow, so corrective cranial surgery early in life may be necessary. This surgery is generally successful, although some skull malformation may remain. Additional surgery is sometimes employed to reduce the oversized lower jaw and to at least partially correct protruding eyes, although the severity of the eye bulge sometimes fades as the child grows. Depending on the specific malformations, other surgeries may be recommended.

Crouzonodermoskeletal syndrome is a genetic disorder that cannot be prevented. Adults who have the disorder may want to undergo genetic counseling before deciding to have children so that they understand both the risks of passing on the disorder and/or the availability of preimplantation diagnosis via assisted reproduction technologies to ensure that an implanted embryo does not carry the mutation.

Prognosis

Infants are born with symptoms of Crouzonodermoskeletal syndrome. With early surgery to provide for proper brain development, individuals with this disorder do very well and live long and productive lives.

Cystic fibrosis

Definition

Cystic fibrosis (CF) is an inherited disease that affects the lungs, digestive system, sweat glands, and fertility. Its name derives from the fibrous scar tissue that develops in the pancreas, one of the principal organs affected by the disease.

Description

Cystic fibrosis affects the body's ability to move salt and water in and out of cells. This defect causes the lungs and pancreas to secrete thick mucus, blocking passageways and preventing proper function.

Genetic profile

Cystic fibrosis is caused by a pathogenic variant (mutation) in the *CFTR* gene. Genes, found in the nucleus of all of the body's cells, contain the instructions for the production of proteins. Proteins carry out a wide variety of functions within cells. *CFTR* stands for cystic fibrosis transmembrane conductance regulator. A simple change in this gene leads to all of the consequences of CF. There are over 500 known variants in the *CFTR* gene that can cause CF. However, 70% of all people with CF have the same variant, known as delta-F508.

Genes can be thought of as long strings of chemical words, each made of chemical letters, called nucleotides. Just as a sentence can be changed by rearranging its letters, the sequence of nucleotide letters of genes can be changed. If the change causes problems, then it is called a pathogenic variant (mutation). The gene variants in CF are called point mutations, meaning that the gene is changed only at one small spot along its length. The delta-F508 mutation results from the loss of one "letter" out of thousands within the *CFTR* gene. As a result, the *CFTR* protein made from its blueprint is made incorrectly and cannot perform its function properly.

The role of the *CFTR* protein is to allow chloride ions to exit the mucus-producing cells. When the chloride ions leave these cells, water follows, thinning the mucus. Mucus is a complex mixture of salts, water, sugars, and proteins that cleanses, lubricates, and protects many passageways in the body, including those in the lungs and pancreas. The *CFTR* protein helps to keep mucus from becoming thick and sluggish, thus allowing it to be moved steadily along the passageways to aid in cleansing.

In CF, the *CFTR* protein does not allow enough chloride ions out of the mucus-producing cells. With less chloride leaving, less water leaves, and the mucus becomes thick and sticky. It can no longer move freely through the passageways, so they become clogged. In the pancreas, clogged passageways prevent secretion of digestive enzymes into the intestine, causing serious impairment of digestion—especially of fat—which may lead to malnutrition. Mucus in the lungs may plug the airways, preventing good air exchange and, ultimately, leading to emphysema. The mucus is also a rich source of nutrients for bacteria, leading to frequent infections.

To understand the inheritance pattern of CF, it is important to realize that genes actually have two functions. First, as noted above, they serve as the blueprint for the production of proteins. Second, they are the material of inheritance: parents pass on characteristics to their

children by combining the genes in egg and sperm to make a new individual.

Each person has two copies of each gene, including the *CFTR* gene, in each of his or her body cells. During sperm and egg production, however, these two copies separate, so that each sperm or egg contains only one copy of each gene. When sperm and egg unite, the newly created cell once again has two copies of each gene.

The two gene copies may be the same or they may be different. For the *CFTR* gene, for instance, a person may have two normal copies, one copy with a variant and one normal copy or two copies with a variant. A person who has pathogenic variants in both copies of the *CFTR* gene will develop cystic fibrosis. A person with one variant is said to be a carrier. Most carriers of CF do not have symptoms, although research suggests that carriers may have a higher risk of CF related problems. Carriers but can pass on the *CFTR* gene variant to his or her children.

When two carriers have children, they have a one in four (25%) chance of having a child with CF each time they conceive. They have a two in four chance of having a child who is a carrier (50%), and a one in four (25%) chance of having a child with two normal *CFTR* genes.

Demographics

CF affects approximately 35,000 children and young adults in the United States, and about 3,500 babies are born with CF every year. CF primarily affects people of Northern European descent; rates are much lower in non-Caucasian populations.

Approximately 1 in every 25 Americans of Northern European descent is a CF carrier, while only 1 in 17,000 African-Americans and 1 in 30,000 Asian-Americans

are carriers. Since carriers may be symptom-free, many people are unaware that they are carriers, unless they have a family history of the disease. Two Caucasian Americans with no family history of CF have a 1 in 2,500 chance of having a child with CF.

It may seem puzzling that gene variant with such harmful consequences would remain so common. You might think that the high mortality of CF would quickly lead to loss of the abnormal gene variants from the population. Some researchers believe that CF gene variants persist in the population because they protect carriers from cholera. Cholera is a microorganism that infects the intestine, causing intense diarrhea and eventual death by dehydration. This so-called heterozygote advantage can be seen in other genetic disorders.

Signs and symptoms

The most severe effects of cystic fibrosis are seen in two body systems: the gastrointestinal (digestive) system and the respiratory tract from the nose to the lungs. CF also affects the sweat glands and male fertility. Symptoms develop gradually, with gastrointestinal symptoms often the first to appear.

Gastrointestinal system

Ten to fifteen percent of babies who inherit CF have meconium ileus at birth. Meconium is the first dark stool that a baby passes after birth; ileus is an obstruction of the digestive tract. The meconium of a newborn with meconium ileus is thickened and sticky, due to the presence of thickened mucus from the intestinal glands. Meconium ileus causes abdominal swelling and vomiting, and often requires surgery immediately after birth.

Presence of meconium ileus is considered highly indicative of CF. Borderline cases may be misdiagnosed, however, and attributed instead to a milk allergy.

Other abdominal symptoms are caused by the inability of the pancreas to supply digestive enzymes to the intestine. During normal digestion, as food passes from the stomach into the small intestine, it is mixed with pancreatic secretions, which help to break down the nutrients for absorption. While the intestines themselves also provide some digestive enzymes, the pancreas is the major source of enzymes for the digestion of all types of foods, especially fats and proteins.

In CF, thick mucus blocks the pancreatic duct, which is eventually closed off completely by scar tissue formation, leading to a condition known as pancreatic insufficiency. Without pancreatic enzymes, large amounts of undigested food pass into the large intestine. Bacterial action on this rich food source can cause gas and abdominal swelling. The large amount of fat remaining in the feces makes it bulky, oily, and foul-smelling.

Because nutrients are only poorly digested and absorbed, the person with CF is often ravenously hungry, underweight, and shorter than expected for his age. When CF is not treated for a longer period, a child may develop symptoms of malnutrition, including anemia, bloating, and paradoxically, appetite loss.

Diabetes becomes increasingly likely as a person with CF ages. Scarring of the pancreas slowly destroys those pancreatic cells that produce insulin, producing type I, or insulin-dependent, diabetes.

Gallstones affect approximately 10% of adults with CF. Liver problems are less common, but can be caused by the buildup of fat within the liver. Complications of liver enlargement may include internal hemorrhaging, abdominal fluid (ascites), spleen enlargement, and liver failure.

Other gastrointestinal symptoms can include a prolapsed rectum, in which part of the rectal lining protrudes through the anus; intestinal obstruction; and rarely, intussusception, in which part of the intestinal tube slips over an adjoining part, cutting off blood supply.

Somewhat fewer than 10% of people with CF do not have gastrointestinal symptoms. Most of these people do not have the delta-F508 mutation, but rather a different one, which presumably allows at least some of their *CFTR* proteins to function normally in the pancreas.

Respiratory tract

The respiratory tract includes the nose, the throat, the trachea (or windpipe), the bronchi (which branch off from the trachea within each lung), the smaller bronchioles, and

the blind sacs called alveoli, in which gas exchange takes place between air and blood.

Swelling of the sinuses within the nose is common in people with CF. This usually shows up on x-rays, and may aid the diagnosis of CF. However, this swelling, called pansinusitis, rarely causes problems, and does not usually require treatment.

Nasal polyps, or growths, affect about one in five people with CF. These growths are not cancerous, and do not require removal unless they become annoying. While nasal polyps appear in older people without CF, especially those with allergies, they are rare in children without CF.

The lungs are the site of the most life-threatening effects of CF. The production of a thick, sticky mucus increases the likelihood of infection, decreases the ability to protect against infection, causes inflammation and swelling, decreases the functional capacity of the lungs, and may lead to emphysema. People with CF will live with chronic populations of bacteria in their lungs, and lung infection is the major cause of death for those with CF.

The bronchioles and bronchi normally produce a thin, clear mucus, which traps foreign particles including bacteria and viruses. Tiny hair-like projections called cilia on the surface of these passageways slowly sweep the mucus along, out of the lungs and up the trachea to the back of the throat, where it may be swallowed or coughed up. This “mucociliary escalator” is one of the principal defenses against lung infection.

The thickened mucus of CF prevents easy movement out of the lungs, and increases the irritation and inflammation of lung tissue. This inflammation swells the passageways, partially closing them down, further hampering the movement of mucus. A person with CF is likely to cough more frequently and more vigorously as the lungs attempt to clean themselves out.

At the same time, infection becomes more likely since the mucus is a rich source of nutrients. Bronchitis, bronchiolitis, and pneumonia are frequent in CF. The most common infecting organisms are the bacteria *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*. A small percentage of people with CF have infections caused by *Burkholderia cepacia*, a bacterium which is resistant to most current antibiotics (*Burkholderia cepacia* was formerly known as *Pseudomonas cepacia*). The fungus *Aspergillus fumigatus* may infect older children and adults.

The body's response to infection is to increase mucus production; white blood cells fighting the infection thicken the mucus even further as they break down

and release their cell contents. These white blood cells also provoke more inflammation, continuing the downward spiral that marks untreated CF.

As mucus accumulates, it can plug the smaller passageways in the lungs, decreasing functional lung volume. Getting enough air can become difficult; tiredness, shortness of breath, and intolerance of exercise become more common. Because air passes obstructions more easily during inhalation than during exhalation, over time, air becomes trapped in the smallest chambers of the lungs, the alveoli. As millions of alveoli gradually expand, the chest takes on the enlarged, barrel-shaped appearance typical of emphysema.

For unknown reasons, recurrent respiratory infections lead to digital clubbing, in which the last joint of the fingers and toes becomes slightly enlarged.

Sweat glands

The *CFTR* protein helps to regulate the amount of salt in sweat. People with CF have sweat that is much saltier than normal, and measuring the saltiness of a person's sweat is the most important diagnostic test for CF. Parents may notice that their infants taste salty when they kiss them. Excessive salt loss is not usually a problem except during prolonged exercise or heat. While most older children and adults with CF compensate for this extra salt loss by eating more salty foods, infants and young children are in danger of suffering its effects (such as heat prostration), especially during summer. Heat prostration is marked by lethargy, weakness, and loss of appetite, and should be treated as an emergency condition.

Fertility

Ninety-eight percent of men with CF are sterile, due to complete obstruction or absence of the vas deferens, the tube carrying sperm out of the testes. While boys and men with CF form normal sperm and have normal levels of sex hormones, sperm are unable to leave the testes, and fertilization is not possible. Most women with CF are fertile, though they often have more trouble getting pregnant than women without CF. In both boys and girls, puberty is often delayed, most likely due to the effects of poor nutrition or chronic lung infection. Women with good lung health usually have no problems with pregnancy, while those with ongoing lung infection often do poorly.

Diagnosis

The decision to test a child for cystic fibrosis may be triggered by concerns about recurring gastrointestinal or respiratory symptoms, or salty sweat. A child born with meconium ileus will be tested before leaving the hospital.

Families with a history of CF may wish to have all children tested, especially if there is a child who already has the disease. Some hospitals now require routine screening of newborns for CF.

Sweat test

The sweat test is both the easiest and most accurate test for CF. In this test, a small amount of the drug pilocarpine is placed on the skin. A very small electrical current is then applied to the area, which drives the pilocarpine into the skin. The drug stimulates sweating in the treated area. The sweat is absorbed onto a piece of filter paper, and is then analyzed for its salt content. A person with CF will have salt concentrations that are one-and-one-half to two times greater than normal. The test can be done on persons of any age, including newborns, and its results can be determined within an hour. Virtually every person who has CF will test positive on it, and virtually everyone who does not will test negative.

Collecting enough sweat for the sweat test from infants can be challenging. Currently, a bulky device that fits around the wrist must be worn for 30 minutes. This device can be uncomfortable for the baby and may not be able to collect enough sweat. Researchers from Northwestern University have developed a sticker placed on the skin that measures salt content. This sticker can provide a diagnosis of cystic fibrosis in minutes by changing color. It is more comfortable to wear and collects 33% more sweat than current devices. The sticker also has color sensors, which allows health providers to measure chloride concentration through a smartphone picture.

Genetic testing

The discovery of the *CFTR* gene in 1989 allowed the development of an accurate genetic test for CF. Genes from a small blood or tissue sample are analyzed for specific variants. The presence of a variant in both copies of the *CFTR* gene confirms the diagnosis of CF. In some rare cases of CF, a variant is not detected. This could be because the test done did not look for all variants or the variant in this person has not yet been discovered.

Couples planning a family may decide to have themselves tested. Testing is recommended if they are Caucasian and of European ancestry, or if one or both have a family history of CF. Prenatal genetic testing is possible through amniocentesis. Many couples who already have one child with CF decide to undergo prenatal screening in subsequent pregnancies. Siblings in these families are also usually tested, both to determine if they will develop CF, and to determine if they are carriers, to aid in their

KEY TERMS

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

CFTR—Cystic fibrosis transmembrane conductance regulator. The protein responsible for regulating chloride movement across cells in some tissues. When a person has two defective copies of the *CFTR* gene, cystic fibrosis is the result.

Emphysema—A chronic lung disease that begins with breathlessness during exertion and progresses to shortness of breath at all times, caused by destructive changes in the lungs.

Mucociliary escalator—The coordinated action of tiny projections on the surfaces of cells lining the respiratory tract, which moves mucus up and out of the lungs.

Mucolytic—An agent that dissolves or destroys mucin, the chief component of mucus.

Pancreatic insufficiency—Reduction or absence of pancreatic secretions into the digestive system due to scarring and blockage of the pancreatic duct.

own family planning. If the sibling has no symptoms, determining his or her carrier status is often delayed until the teen years or later, when he or she is closer to needing the information to make decisions.

Newborn screening

Some states now require screening of newborns for CF, using a test known as the IRT test. This is a blood test which measures the level of immunoreactive trypsinogen, which is generally higher in babies with CF than those without it. This test gives many false positive results immediately after birth, and so requires a second test several weeks later. A second positive result is usually followed by a sweat test.

Treatment and management

There is no cure for cystic fibrosis. Treatment has advanced considerably in the past several decades, increasing both the lifespan and the quality of life for most people affected by CF. Early diagnosis is important to prevent malnutrition and infection from weakening the young child. With proper management, many people with CF engage in the full range of school and sports activities.

Nutrition

People with CF usually require high-calorie diets and vitamin supplements. Height, weight, and growth of a person with CF are monitored regularly. Most people with CF need to take pancreatic enzymes to supplement or replace the inadequate secretions of the pancreas. Tablets containing pancreatic enzymes are taken with every meal; depending on the size of the tablet and the meal, as many as 20 tablets may be needed. Because of incomplete absorption even with pancreatic enzymes, a person with CF needs to take in about 30% more food than a person without CF. Low-fat diets are *not* recommended except in special circumstances, since fat is a source of both essential fatty acids and abundant calories.

Some people with CF cannot absorb enough nutrients from the foods they eat, even with specialized diets and enzymes. For these people, tube feeding is an option. Nutrients can be introduced directly into the stomach through a tube inserted either through the nose (a nasogastric tube) or through the abdominal wall (a gastrostomy tube). A jejunostomy tube, inserted into the small intestine, is also an option. Tube feeding can provide nutrition at any time, including at night while the person is sleeping, allowing constant intake of high-quality nutrients. The feeding tube may be removed during the day, allowing normal meals to be taken.

Respiratory health

The key to maintaining respiratory health in a person with CF is regular monitoring and early treatment. Lung function tests are done frequently to track changes in functional lung volume and respiratory effort. Sputum samples are analyzed to determine the types of bacteria present in the lungs. Chest x-rays are usually taken at least once a year. Lung scans, using a radioactive gas, can show closed off areas not seen on the x-ray. Circulation in the lungs may be monitored by injection of a radioactive substance into the bloodstream. Artificial intelligence software can also be used to analyze CT scans to help detect and analyze lung abnormalities.

People with CF live with chronic bacterial colonization; that is, their lungs are constantly host to several species of bacteria. Good general health, especially good nutrition, can keep the immune system healthy, which decreases the frequency with which these colonies begin an infection, or attack on the lung tissue. Exercise is another important way to maintain health, and people with CF are encouraged to maintain a program of regular exercise.

In addition, clearing mucus from the lungs helps to prevent infection, and mucus control is an important aspect of CF management. Bronchial drainage is used to

allow gravity to aid the mucociliary escalator. For this technique, the person with CF lies on a tilted surface with head downward, alternately on the stomach, back, or side, depending on the section of lung to be drained. An assistant thumps the rib cage to help loosen the secretions. A device called a “flutter” offers another way to loosen secretions: it consists of a stainless steel ball in a tube. When a person exhales through it, the ball vibrates, sending vibrations back through the air in the lungs. Some special breathing techniques may also help clear the lungs.

Several drugs are available to prevent the airways from becoming clogged with mucus. Bronchodilators can help open up the airways; steroids reduce inflammation; and mucolytics loosen secretions. Acetylcysteine (Mucomyst) has been used as a mucolytic for many years but is not prescribed frequently now, while dornase alfa (Pulmozyme) is a newer product gaining in popularity. Dornase alfa breaks down the DNA from dead white blood cells and bacteria found in thick mucus.

People with CF may pick up bacteria from other CF patients. This is especially true of *Burkholderia cepacia*, which is not usually found in people without CF. While the ideal recommendation from a health standpoint might be to avoid contact with others who have CF, this is not usually practical (since CF clinics are a major site of care), nor does it meet the psychological and social needs of many people with CF. At a minimum, CF centers recommend avoiding prolonged close contact between people with CF; and scrupulous hygiene, including frequent hand washing. Some CF clinics schedule appointments on different days for those with and without *B. cepacia* colonies.

Some doctors choose to prescribe antibiotics only during infection, while others prefer long-term antibiotic treatment against *S. aureus*. The choice of antibiotic depends on the particular organism or organisms found. Some antibiotics are given as aerosols directly into the lungs. Antibiotic treatment may be prolonged and aggressive.

Supplemental oxygen may be needed as lung disease progresses. Respiratory failure may develop, requiring temporary use of a ventilator to perform the work of breathing.

Lung transplantation is another option for people with CF, although the number of people who receive them is still much lower than those who want them. Transplantation is not a cure, however, and has been likened to trading one disease for another. Long-term immunosuppression is required, increasing the likelihood of other types of infection. About 50% of adults and more than 80% of children who receive lung transplants live

longer than two years. Some CF patients whose livers have been damaged by fibrosis also undergo liver transplants.

Long-term use of ibuprofen has been shown to help some people with CF; presumably by reducing inflammation in the lungs. Close medical supervision is necessary, however, since the effective dose is high and not everyone benefits. Ibuprofen at the required doses interferes with kidney function, and together with aminoglycoside antibiotics, may cause kidney failure.

A number of experimental treatments are currently the subject of much research. Some evidence indicates that aminoglycoside antibiotics may help overcome the genetic defect in some CF mutations, allowing the protein to be made normally. While promising, these results would apply to only about 5% of those with CF.

Gene therapy is currently the most ambitious approach to curing CF. In this set of techniques, non-defective copies of the *CFTR* gene are delivered to affected cells, where they are taken up and used to create the *CFTR* protein. While elegant and simple in theory, gene therapy has met with a large number of difficulties in trials so far, including immune resistance, very short duration of the introduced gene, and inadequately widespread delivery.

CFTR modulators

CFTR modulators are a class of drugs that improve or restore the function of the *CFTR* protein but only work for people with certain *CFTR* gene variants. There are three types of *CFTR* modulators currently in development: potentiators, correctors, and amplifiers. Only potentiators and correctors have been approved by the FDA.

Potentiators work by increasing the chances that the *CFTR* protein gate will be open to allow more chloride to flow through the cell membrane. The drug ivacaftor

(Kalydeco) is an example. Potentiators work for people who have CFTR gene variants where the protein produced is normal but is produced in an insufficient amount or where the CFTR protein gate does not work properly.

Correctors help the CFTR protein form a normal shape, move to the cell surface, and stay there longer. Lumacaftor, elxacaftor, and tezacaftor are examples of correctors. Correctors do not work well enough by themselves, since they do not allow enough of the proteins to reach the cell surface and do not allow enough chloride to pass out of the cell. Correctors are therefore usually combined with potentiators like ivacaftor. Trikafta and Symdeko are examples of drugs that combine correctors and potentiators.

Prognosis

People with CF may lead relatively normal lives but in many cases will have a reduced lifespan. Because of better and earlier treatment, a person born today with CF is expected on average to live into their mid-40s. Many of the symptoms of CF can be treated with drugs or nutritional supplements. Close attention to, and prompt treatment of, respiratory and digestive complications have dramatically increased the expected lifespan of a person with CF. Several decades ago, most children with CF died by the age of two; today, about half of all people with CF live past age 31. That median age is expected to grow as new treatments are developed, and it is estimated that a person born in 2021 with CF will likely live to their 40s and beyond. The possible effect of pregnancy on the health of a woman with CF requires careful consideration before beginning a family, as do issues of longevity and her children's status as carriers. Although most men with CF are functionally sterile, new procedures for removing sperm from the testes are being tried, and may offer more men the chance to become fathers.

Cystinosis

Definition

Cystinosis is a rare genetic metabolic disease that causes cystine, an amino acid, to accumulate in lysosomes (organelles within cells that contain enzymes) of various organs of the body, such as the kidneys, liver, eyes, muscles, pancreas, brain, and white blood cells. Although cystinosis primarily affects children, a form of the disease also occurs in adults.

Description

In cystinosis, the cystine content of cells increases to an average of 50 to 100 times its normal value. This

increase is caused by an abnormality in the transport of cystine out of a sac-like compartment of the cell called the lysosome. Because of cystine's low solubility in water, this amino acid forms crystals that accumulate within the lysosomes of cells. The accumulation of cystine is believed to destroy the cells.

There are three basic forms of cystinosis: infantile nephropathic cystinosis; late-onset nephropathic cystinosis; and benign non-nephropathic cystinosis.

Infantile nephropathic cystinosis

Children with infantile cystinosis usually appear normal at birth and during the first six to eight months of life. As Fanconi syndrome (a tubular dysfunction of the kidneys causing impairment in the kidneys' ability to reabsorb minerals and nutrients back into the bloodstream) develops, sodium and water depletion occurs, leading to polyuria (excessive urination) and polydipsia (excessive thirst). Affected children become especially vulnerable to dehydration. This tubular abnormality, in addition to an abnormality in sweat production, often leads to recurrent fevers as a presenting symptom.

By one year of age, children with infantile cystinosis generally exhibit growth retardation; rickets (inadequate deposition of minerals in developing cartilage and newly formed bone, causing abnormalities in shape and structure of bones); metabolic acidosis (excessive acid in the blood); and other chemical evidence of renal tubular abnormalities of the kidney, such as increased renal (kidney) excretion of glucose, amino acids, phosphate, and potassium. However, more subtle clinical and biochemical evidence of the disease can be detected at a much earlier age by careful examination of at-risk children (those with a sibling or other relative with the disease). As a child with infantile nephropathic cystinosis ages, failure to thrive is apparent.

Without therapeutic intervention, children with this disorder remain below the norm in both height and weight throughout life. The typical patient with infantile nephropathic cystinosis has short stature, retinopathy (retinal disorder), photophobia (light sensitivity), and onset of Fanconi syndrome in the first year of life. By one to two years of age, corneal cystine crystals and rickets are evident. Glomerular failure (the glomerulus is a small structure in the kidney made up of a cluster of capillaries) progresses, and end-stage renal disease occurs by about nine to ten years of age.

Late-onset nephropathic cystinosis

In late-onset nephropathic cystinosis, the age of onset ranges from 2 to 26 years; however, the typical age at which the condition presents is 12 to 13 years. If more than

one sibling develops late-onset cystinosis, their age of onset and symptoms are generally similar. Patients with this condition develop crystalline deposits in the cornea and conjunctivae (mucous membranes lining the eyelids), as well as in the bone marrow. Although patients with late-onset cystinosis often do not develop full-blown Fanconi syndrome, renal failure progresses to such a degree that kidney transplantation is necessary, as in the case of infantile nephropathic cystinosis. These individuals are usually in end-stage renal failure within a few years of diagnosis.

Benign non-nephropathic cystinosis

Formerly known as adult cystinosis, benign non-nephropathic cystinosis is usually discovered by chance when an ophthalmologic (eye) examination reveals crystalline opacities within the cornea and conjunctiva. As in patients with infantile nephropathic cystinosis, those with benign cystinosis may also have photophobia; however, light sensitivity may not develop until middle age and is usually not as debilitating. Because the only patients diagnosed with benign cystinosis are those who undergo slit-lamp (a lamp constructed such that intense light is emitted through a slit) eye examination by an eye specialist, it is possible that many individuals with this form of the disease never experience eye symptoms and are never diagnosed. Patients with benign cystinosis develop crystalline deposits in their bone marrow and white blood cells, but do not develop renal dysfunction or retinopathy.

Genetic profile

Cystinosis is an autosomal recessive genetic disease. The term "autosomal" refers to a gene situated on one of the 23 pairs of chromosomes other than a sex chromosome (the X or Y chromosomes). The term "recessive"

KEY TERMS

Cystine—A sulfur-containing amino acid, sometimes found as crystals in the kidneys or urine, that forms when proteins are broken down by digestion.

Fanconi syndrome—A disorder of reabsorption in the kidney tubules.

Glomerulus (plural, glomeruli)—A structure in the kidney composed of blood vessels that are actively involved in the filtration of the blood.

Lysosome—A membrane-enclosed compartment in cells, containing many hydrolytic enzymes; where large molecules and cellular components are broken down.

Nephropathy—Kidney disease.

Photophobia—Extreme sensitivity to light.

Retinopathy—Any disorder of the retina.

refers to an allele, or a form of a gene that may be expressed and/or active; however, the “dominant” form of the gene on the other chromosome usually takes over enough of the gene’s normal function to prevent symptoms of a disorder. Each parent of a child with cystinosis carries one abnormal (recessive) gene and one normal gene. Thus, the child must inherit an abnormal (or altered) gene from each parent to develop the disease. In addition, when a child develops cystinosis, the parents are almost always surprised because they never exhibited any symptoms of the disease. The recessive gene may lie dormant for generations until two people with the abnormal gene come together and have children.

Each time two such cystinosis carriers—persons with one copy of the altered gene and one copy of a normal or functioning gene—have a child together, there is a 1-in-4 chance (25% risk) of having a child with cystinosis; a 2-in-4 chance (50% risk) the child will not have cystinosis but will be a carrier; and a 1-in-4 chance the child will not have cystinosis or be a carrier. Also, every unaffected sibling of a child with cystinosis has a 2-in-3 (67%) chance of being a carrier (having one copy of the abnormal gene and one copy of a normal gene), like his or her parents.

Scientists have mapped the cystinosis gene, *CTNS*, to the short arm of chromosome 17 (at location 17p13). Mutations (changes) in the cystinosis gene (specifically, a deletion of a particular part of the gene) have been found to cause all three types of cystinosis. However, this deletion is difficult to identify in some individuals for reasons that are uncertain. In these individuals, extensive

and very sophisticated laboratory work (molecular genetic testing) to identify and prove the existence of the deletion would be necessary.

In patients of Northern European descent, for example, there is about a 50/50 probability that an individual with cystinosis has the deletion. Genetic testing is under investigation for populations of these regions, but until details of the methodology are refined, measurement of lysosomal cystine in white cells and fibroblasts (any cell or corpuscle from which connective tissue is developed) will remain state-of-the-art and the most broadly based general method for diagnosing cystinosis. Molecular genetic testing for mutations of the *CTNS* gene was, however, available at several laboratories in the United States as of 2021. The tests involve deletion/duplication analysis or sequence analysis of the entire coding region.

Demographics

It is estimated that 2,000 individuals worldwide have cystinosis, although exact figures are difficult to obtain because the disease often remains undiagnosed. In the United States, the disease is believed to affect 1 in every 100,000 to 200,000 live births, or approximately 400 individuals, with about 15 new cases identified each year. Cystinosis is more common in Brittany, a province of France, where it affects about 1 person in every 26,000. In Canada, the disorder is more common among French Canadians living in Quebec than among English-speaking Canadians in the other provinces. The male:female ratio in cystinosis is about 1.4:1.

Signs and symptoms

Although the symptoms of cystinosis vary depending on the type of disease present, general symptoms include the following:

- acidosis
- dehydration
- rickets
- growth retardation
- renal glomerular failure
- corneal ulcerations and retinal blindness
- delayed puberty
- swallowing difficulties

Diagnosis

Cystinosis may be diagnosed prenatally by examining cystine levels in chorionic villi (obtained by chorionic villus sampling, usually done at 10–12 weeks gestation) or in cells contained in amniotic fluid (obtained by amniocentesis, usually done at 16–18 weeks gestation).

In early infancy, cystinosis is usually diagnosed by measuring free cystine in white blood cells and skin fibroblasts.

Chorionic villus sampling

Chorionic villus sampling (tissue sample of tiny pieces of placental tissue obtained by inserting a thin needle or narrow tube into the uterus) is performed at 10–12 weeks of gestation. Intracellular cystine levels are measured. The values in a fetus with cystinosis are more than ten times greater than normal.

Amniocentesis

Amniocentesis (sample of amniotic fluid obtained by inserting a thin needle into the uterus) can be performed at 16–18 weeks gestation.

White blood cell testing

When diagnosed early, the progressive kidney failure, retarded growth, and vision problems can be prevented or delayed by proper management and medication. The metabolic abnormality in cystinosis is the failure of the cellular lysosomes to release cystine. As a result, the free cystine in the lysosomes accumulates to many times the normal value. The diagnosis of cystinosis is therefore based in part on the measurement of free cystine in the tissues that accumulate this amino acid. This measurement is most easily accomplished in white blood cells. Whole blood contains red cells, which are rich in glutathione, a compound that can react with cystine. To prevent this reaction, white cells are separated from red cells. The white cells are kept cold to slow down reactions, and then broken open and frozen. Freezing prevents the reaction of cystine with such compounds as glutathione and precipitates the cell protein. These steps stabilize the cystine content of the preparation.

Skin fibroblast testing

Cultured skin fibroblasts may also be used to diagnose cystinosis. Because of the increased time and costs, white blood cells are usually sent for testing first. Skin fibroblast testing (biopsy) is also more invasive than a blood sample. On rare occasions the expression of the abnormality in white cells is borderline for diagnosis. Thus, confirmation using fibroblasts is definitive.

Treatment and management

Cystinosis is treated by a variety of pharmacologic and nonpharmacologic therapies, as well as by surgical transplantation.

QUESTIONS TO ASK YOUR DOCTOR

- How do the three types of cystinosis differ from one another?
- What did my physician mean when he recommended cysteamine treatment for my child with cystinosis?
- If my child stays on cysteamine throughout his life, will he be spared the worst consequences of this disease?
- What services does the Cystinosis Foundation provide for parents of children with the disorder? For adults with the condition?

Pharmacologic therapy

The aim of specific treatment for cystinosis is to reduce cystine accumulation within the cells. This goal is achieved by cysteamine treatment, which has proven effective in delaying or preventing renal failure. Cysteamine treatment also improves growth in children with cystinosis. The growth improvement with cysteamine bitartrate usually allows the patient to maintain growth along a percentile but does not usually aid in achieving catch-up growth.

The Food and Drug Administration (FDA) approved a capsule form of cysteamine bitartrate called Cystagon in August 1994. However, oral cysteamine does not prevent the progression of ocular lesions and has many potential side effects. Little is known about the drug's long-term effects. The main disadvantage of cysteamine treatment is the need for four daily capsules (every six hours) and the sulfurous breath it causes. Cysteamine treatment is also expensive. In 2013, the FDA approved Procysbi, an extended-release formulation of cysteamine, for the treatment of cystinosis in adults and children over six years of age. This formulation is taken only twice a day, or every 12 hours.

Many children with cystinosis receive growth hormone, and some have had improvements in height. There is also evidence that indomethacin (Indocin) increases appetite, decreases urine volume, decreases water consumption, and improves growth in pretransplanted patients with cystinosis.

Vitamin/mineral supplementation

The symptomatic treatment of Fanconi syndrome is essential in patients with cystinosis. The urinary losses of water, salts, bicarbonate, and minerals must be replaced.

Most children receive a solution of sodium and potassium citrate as well as phosphate. Some also receive extra vitamin D.

Organ transplantation

Kidney transplantation has proven useful in patients with cystinosis. If a patient with cystinosis receives a kidney transplant and reaches adulthood, the new kidney will not be affected by the disease. However, without cysteamine treatment, kidney transplant recipients can develop complications in other organs due to the continued cystine accumulation in the body. These complications can include muscle wasting, difficulty swallowing, diabetes, hypothyroidism, and blindness. Not all older patients, however, develop these symptoms.

In both young children with cystinosis and older patients with a kidney transplant, cysteamine eye drops may be useful in removing the corneal cystine crystals and reducing photophobia. In 2013, the FDA approved an ophthalmic solution of cysteamine called Cystaran for the treatment of cystine crystals in the cornea of the eye.

Prognosis

Since 1980, the prognosis of a child with cystinosis has greatly improved. However, if children with the disease receive no treatment, they rarely survive past the age of nine or ten. As of 2021, with proper treatment, many patients survive into the third or fourth decade of life.

Cystinuria

Definition

Cystinuria is a relatively common inherited disorder characterized by the formation of cystine urinary tract stones that can lead to obstruction, infection, and eventual loss of renal function.

Description

In cystinuria, there is a defect in the movement of cystine and the dibasic amino acids (lysine, arginine, and ornithine) across the epithelial cells of the kidneys and the small intestine. In the kidney, most amino acids are filtered by the glomerulus and reabsorbed by the proximal tubules with little residual amino acid in the urine. In cystinuria, cystine and the dibasic amino acids are not reabsorbed by the tubules of the kidney, and eventually build up in the urine. Cystine in high concentrations is insoluble in urine and will form stones (calculi) in the kidneys, bladder, and ureters. The transport defect in the small intestine leads to the accumulation of digestion breakdown products of cystine and the dibasic amino acids in the stool, urine, and plasma. The intestinal defect does not appear to result in any adverse symptoms for the affected individual.

Cystinuria has been classified into three types (I, II, and III) based on the urinary excretion of cystine and the dibasic amino acids among carriers of the disease

(heterozygotes), and on the nature of the intestinal transport defect among affected individuals (homozygotes).

The name cystine is derived from the Greek word for bladder, “kystis.” When the disease was first described in the 1800s, it was thought that the origin of the cystine stones was the bladder. Historically, cystinuria is important because it was one of the four inborn errors of metabolism reported by Sir Archibald Garrod in his famous Croonian Lecture in 1908. Although alternate names for the disorder include cystine-lysinuria, cystine-lysine-arginine-ornithinuria, and cystinuria dibasic aminoaciduria, the term “cystinuria” is used most often to describe the disease.

Genetic profile

Cystinuria is a complex autosomal recessive disorder. Type I cystinuria is completely recessive; carriers have no manifestations. Types II and III cystinuria are incompletely recessive; carriers can display symptoms. Two amino acid transporter genes, *SLC3A1* (solute carrier family 3, member 1) located on chromosome 2p, and *SLC7A9* (solute carrier family 7, member 9) located on chromosome 19q, are known to cause cystinuria. The proteins produced by these two genes apparently interact with one another. An individual with two mutations in the *SLC3A1* gene (homozygote) has type I disease. Mutations in the *SLC7A9* gene lead to types II and III cystinuria. Types II and III cystinuria are allelic; different changes (mutations) in the same gene lead to alternative forms of the disease. There are some patients who are genetic compounds—they have a type II mutation on one copy of the gene and a type III mutation on the other copy. There are also individuals who may have mutations in both the *SLC3A1* gene and the *SLC7A9* gene.

Demographics

Cystinuria is considered one of the more common genetic disorders with an estimated prevalence of 1 in 7,000. Most affected individuals have type I disease. Type II disease is relatively rare. Due to a founder effect, an increased incidence of cystinuria exists among individuals of Libyan Jewish ancestry. Approximately 1 in 2,500 persons of Libyan Jewish descent has type II disease. The carrier frequency in this population is around 1 in 25.

Signs and symptoms

Symptoms of cystinuria develop due to the high level of cystine in the urine. Since cystine at high concentrations is insoluble in urine, undissolved cystine accumulates in the urine and affected individuals are prone to recurrent urinary tract stone formation (nephrolithiasis). Also, hexagonal-shaped crystals form in the urine; these

crystals signify the presence of cystine in potentially stone-forming concentrations. The onset of cystinuria is variable and symptoms can appear anytime between the first year of life and the ninth decade. Most cystinurics develop symptoms in the second and third decades of life. In many affected individuals the first sign of the disorder is renal colic, a painful condition caused by obstruction of the urinary tract. Obstruction of the urinary tract due to calculi can lead to infection and eventually to renal insufficiency. Less often, complaints such as infection, hypertension, and renal failure are the first reasons cystinuric patients seek medical attention.

Unlike most autosomal recessive disorders, carriers for types II and III cystinuria can be symptomatic. Type II carriers have high urinary excretion of cystine and lysine, and type II carriers have moderate excretion of cystine, lysine, arginine, and ornithine. Both type II and type III carriers are at risk to develop stones. Type I carriers have no excess cystine or dibasic amino acids in their urine, and are without symptoms of the disorder.

Although there are reports of an association between cystinuria and neurologic abnormalities, little is known about the mechanism responsible for this, nor is the prevalence of this complication among affected individuals known.

Diagnosis

The diagnosis of cystinuria is made at the biochemical level. Molecular (genetic) testing is also available but is generally not the first means of making a cystinuria diagnosis. The simplest approach to diagnosis of this condition is microscopic examination of the urine for the characteristic hexagonal-shaped crystals. Urinary microscopic examination was the primary means of cystinuria diagnosis for many years since the discovery of these crystals by Stromeyer in 1824, and it remains a useful aid in the diagnosis of this condition today. Another widely used screening procedure is the cyanide-nitroprusside test, a test that measures the amount of cystine excreted in the urine in comparison to the amount of creatinine (a protein normally found in urine). In those patients who display crystals and have a positive nitroprusside test, further diagnostic tests such as thin-layer chromatography or high-voltage electrophoresis can identify the specific amino acids (cystine, lysine, arginine, ornithine); and other techniques such as ion-exchange chromatography, liquid chromatography-mass spectrophotometer, and high-performance liquid chromatography may be performed to measure the amounts of these amino acids in the urine.

The type (I, II, or III) of cystinuria in an affected patient can be determined by family studies and/or by study of the intestinal transport defect in an affected

KEY TERMS

Alkalinization—The process of making a solution more basic, rather than more acidic, by raising the pH.

Allelic—Related to the same gene.

Amino acid—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (eight are essential amino acids, which the body cannot make and must therefore be obtained from food).

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Catheter—A narrow, flexible tube used to create a pathway for introducing drugs, nutrients, fluids, or blood products into the body and/or for removing fluid or other substances from the body.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Cystine—A sulfur-containing amino acid, sometimes found as crystals in the kidneys or urine, that forms when proteins are broken down by digestion.

Epithelial cells—The layer of cells that cover the open surfaces of the body such as the skin and mucous membranes.

Founder effect—Increased frequency of a gene mutation in a population that was founded by a

small ancestral group of people, at least one of whom was a carrier of the gene mutation.

Glomerulus—A structure in the kidney composed of blood vessels that are actively involved in the filtration of the blood.

Homozygote—Having two identical copies of a gene or chromosome.

Obligate carrier—An individual who, based on pedigree analysis, must carry a genetic mutation for a particular genetic disease. Parents of a child with an autosomal recessive disorder are obligate carriers.

Oral loading test—A procedure in which cystine is administered orally to a patient and plasma levels of cystine are measured. Under normal circumstances, amino acids are absorbed by the intestine and result in an increase in plasma amino acid levels. However, in cystinuria, there is a problem in the absorption process and blood levels of amino acids do not rise, or rise slowly after eating.

Plasma—The liquid part of the blood and lymphatic fluid that contains antibodies and other proteins.

Renal—Related to the kidneys.

Renal colic—A spasmodic pain, moderate to severe in degree, located in the back, side, and/or groin area.

Small intestine—The part of the digestive tract that lies between the stomach and the large intestine.

Tubule—A small tube lined with glandular epithelium in the kidney.

Ureters—Tubes through which urine is transported from the kidneys to the bladder.

individual. Type I obligate carriers have normal amounts of urinary cystine and dibasic amino acids. Type II carriers have between nine and fifteen times the normal amount of cystine and lysine in their urine. Type III carriers have up to twice the normal range of cystine and the dibasic amino acids in their urine. The intestinal absorption defect in an affected individual can be demonstrated by oral loading tests and/or by study of the transport of cystine and the dibasic amino acids in an intestinal biopsy specimen from an affected individual.

Testing for mutations in the *SLC3A1* gene and the *SLC7A9* gene is possible. Over 40 mutations in the *SLC3A1* gene have been found and almost as many have been detected in the *SLC7A9* gene.

Treatment and management

Prevention

The primary goal of treatment of cystinuria is prevention of existing cystine stones through noninvasive means. There are three main categories of treatment: increase cystine solubility, reduce cystine production and excretion, and convert cystine into a more soluble compound. The first step in treatment is to increase cystine solubility via hydration therapy. It is recommended that patients increase their fluid intake such that the concentration of cystine is 200-250 mg/liter of urine. This therapy prevents stone formation approximately two-thirds of the time. Another therapy that increases cystine

QUESTIONS TO ASK YOUR DOCTOR

- Please explain the process by which stones form in the kidney as a result of cystinuria.
- How do the various types of cystinuria differ from each other?
- Under what circumstances, if any, is surgery required for the treatment of my cystinuria?
- How does a physician diagnose a case of cystinuria, and how does that diagnosis distinguish the disease from similar medical conditions?

solubility is known as oral alkalinization. Medications such as sodium citrate, potassium citrate, or sodium bicarbonate increase the pH of urine to levels at which cystine becomes a more soluble compound. To reduce cystine excretion and production, individuals with cystinuria may follow a diet low in sodium and protein.

If the above measures are not successful in preventing stones and/or dissolving existing ones, drug therapy may be necessary. Tiopronin and d-penicillamine are two drugs that are known to bind excess cystine into a form that is more soluble than cystine alone and thus reduce the excessive urinary excretion of this amino acid. Since both tiopronin and d-penicillamine can have adverse side effects, patients on these regimens require follow-up to monitor the efficacy and tolerance of the medication. Other medications that reduce cystine excretion include mercaptopropionylglycine (MPG) and captopril. Although they are not as effective as tiopronin or d-penicillamine, MPG and captopril have fewer side effects.

If stones form despite the above therapeutic regimens, surgical intervention may be required. Surgical management of cystine stones may include dissolution of calculi by irrigation through a catheter, removal of cystine stones by lithotripsy or lithotomy, and renal transplantation. Catheter irrigation is a minimally invasive procedure in which catheters are placed into the ureters and the urinary tract is irrigated with a solution that dissolves the stones over a period of one week to several months. Lithotripsy is a medical procedure used to break a kidney stone into small pieces that can be passed in the urine. In extracorporeal shock wave lithotripsy, a shock

wave produced outside the body is used to break up the stone and a catheter placed in the ureter facilitates passage of the stone fragments. In percutaneous nephrolithotripsy, an opening (port) is created by puncturing the kidney through the skin; a specialist then inserts instruments via this opening into the kidney to break up the stone and remove the debris. Lithotomy is the surgical removal of a (kidney) stone.

Prognosis

The prognosis of cystinuria is variable and depends on the level of renal function at the time of diagnosis and initiation of therapy, and the success of preventive measures and surgical management. It is known that males tend to have a more severe course and a higher mortality rate.

Dandy-Walker malformation

Definition

Dandy-Walker malformation is a congenital (present at birth) condition involving several abnormalities in the development of the brain. The malformation appears to result from destructive processes, such as inflammation or trauma, which block the circulation of cerebrospinal fluid (CSF) inside the head after the brain has been formed in the embryo.

Description

Dandy-Walker malformation was first described in 1914 by Drs. Walter Dandy and Kenneth Blackfan. The disorder typically includes the following abnormalities in brain structure:

- Absence or incomplete formation of the vermis, the middle portion of the cerebellum, which is the part of the human brain that is attached posteriorly to the brainstem.
- Cysts in the fourth ventricle, one of the human brain's four interconnected ventricles (inner cavities or chambers) that produce cerebrospinal fluid (CSF), cause enlargement. In Dandy-Walker malformation, the CSF cannot circulate freely through the ventricles and the rest of the central nervous system (CNS), so it builds up inside the fourth ventricle and causes it to enlarge.
- Enlargement of the posterior fossa, which is a hollow at the back of the skull that contains the cerebellum.
- Absence or incomplete formation of the three apertures (small openings or holes) in the fourth ventricle.

In Dandy-Walker malformation, the CSF produced by the ventricles of the brain is not fully reabsorbed by the body; thus the excess fluid accumulates in the fourth ventricle and the posterior fossa. As cysts in these areas grow, pressure from the fluid rises, producing a condition known as obstructive, or noncommunicating, hydrocephalus (excess fluid on the brain). Hydrocephalus develops

in 20%–80% of children diagnosed with Dandy-Walker malformation. The size of the head may or may not be affected by the fluid pressure.

Genetic profile

The genetic transmission of Dandy-Walker malformation is not fully understood because the disorder often occurs with other birth abnormalities, including cleft palate, extra fingers (polydactyly) or fingers joined together (syndactyly), cataracts, and malformations of the face or heart. An abnormality in the central nervous system that often occurs together with Dandy-Walker malformation is agenesis (absence or failure to develop) of the corpus callosum, the thick band of nerve fibers that joins the two cerebral hemispheres. It is not yet clear whether these and other abnormalities in CNS development are determined by the same gene or whether they are inherited separately.

Dandy-Walker malformation appears to be transmitted in some families in an autosomal, or X-linked, recessive pattern, which means that both parents have one copy of the changed (mutated) gene but do not have the malformation. These families have a high risk of recurrence of the malformation. Families in which there has been inbreeding among close relatives also appear to transmit Dandy-Walker in an autosomal recessive pattern. Several chromosomal abnormalities have been associated with Dandy-Walker.

Demographics

Dandy-Walker malformation is a rare disorder. It is estimated to occur in about 3% of children with hydrocephalus, which occurs in 1–2 per 1,000 births. It appears to affect females more often than males. While there is no known association with specific races or ethnic groups, recent genetic case studies of Dandy-Walker malformation include cases from Argentina, Poland, Germany, Brazil, Austria, and Japan.

Signs and symptoms

Some signs of Dandy-Walker malformation may appear before birth. It is possible to detect hydrocephalus by ultrasound as early as 15–18 weeks after conception. A newborn with hydrocephalus may have difficulty breathing, dilated veins visible on the scalp, and rapid head growth. Infants with Dandy-Walker may be slow to develop motor (movement) skills, and may have abnormally large skulls as a result of the fluid pressure inside the head.

Older children with Dandy-Walker malformation may have symptoms associated with fluid pressure inside the head, including vomiting, convulsions, and emotional irritability. If the cerebellum has been damaged, the child's sense of balance and coordination will be affected. About 20% of older children with Dandy-Walker have difficulty coordinating movements of the hands or feet (ataxia) or have involuntary jerking movements of the eyes (nystagmus). Developmental delays and intellectual disability are more common. In some cases Dandy-Walker may be associated with an abnormal pituitary gland and delayed puberty. Other symptoms that sometimes appear in this group include unusually large head size, a bulge at the back of the head caused by fluid pressure in the posterior fossa, and abnormal breathing patterns.

Diagnosis

About 80% of children with Dandy-Walker malformation are diagnosed before the end of the first year, usually as a result of the signs of hydrocephalus. Following birth, the newborn's head circumference is measured to determine whether it has been enlarged by the development of cysts. As has already been mentioned, ultrasound screening before birth can detect some signs of hydrocephalus. Ultrasound screening is recommended if the family has a history of congenital neurologic abnormalities. Genetic counseling is recommended for parents who have already had a child with Dandy-Walker malformation as there is an increased risk that the malformation will recur in later pregnancies.

Imaging studies used to diagnose and monitor Dandy-Walker include:

- x-rays of the skull to determine that the posterior fossa has been enlarged
- CT scan or magnetic resonance imaging (MRI) tests to evaluate the size and shape of the fourth ventricle, the presence and size of the vermis, and the displacement of other parts of the brain by fluid pressure
- cranial ultrasound to evaluate the size of the ventricle or to assess the progression of hydrocephalus, or

KEY TERMS

Agenesis—Failure of an organ, tissue, or cell to develop or grow.

Congenital—Refers to a disorder that is present at birth.

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides communications between the right and left cerebral hemispheres.

Cyst—An abnormal sac or closed cavity filled with liquid or semisolid matter.

Foramen—A small opening or hole in a body part or tissue.

Hydrocephalus—The excess accumulation of cerebrospinal fluid within the brain, often causing enlargement of the head.

Posterior fossa—Area at the base of the skull that contains the brain stem and cerebellum.

Shunt—A small tube placed in a ventricle of the brain to direct cerebrospinal fluid away from the blockage into another part of the body.

Trisomy—The condition of having three identical chromosomes, instead of the normal two, in a cell.

Ventricle—The fluid-filled spaces in the center of the brain that hold cerebral spinal fluid.

Vermis—The central portion of the cerebellum, which divides the two hemispheres. It functions to monitor and control movement of the limbs, trunk, head, and eyes.

- transillumination, a technique that shines a strong light through an organ or body part to assist in diagnosis. The posterior fossa may be transilluminated as part of the differential diagnosis of Dandy-Walker.

Treatment and management

Treatment of Dandy-Walker malformation is usually focused on managing hydrocephalus when it is present. Hydrocephalus cannot be cured, but it can be treated surgically by placing a shunt in the ventricles of the brain to reduce fluid pressure. The shunt carries some of the CSF into another part of the body where it can be reabsorbed.

Another important part of managing Dandy-Walker is treatment of conditions or abnormalities associated with it—such as giving anticonvulsant medications for

seizures or hormones to bring on puberty that has been delayed.

Prognosis

The prognosis for children with Dandy-Walker malformation is usually not encouraging because of the associated multiple abnormalities. Children with other congenital abnormalities occurring together with Dandy-Walker often do not survive. The affected person's chances of normal intellectual development depend on the severity of the malformation and the presence of other abnormalities.

De novo

Definition

De novo is from the Latin meaning "anew" or "from the beginning." A *de novo* mutation is a change in genetic information that is not inherited from the parents; rather, the mutation occurs in an egg or sperm cell (germ cell or gamete), in the fertilized egg, during embryonic or fetal development, or during the lifetime of an individual. *De novo* mutations can cause genetic disorders ranging from developmental abnormalities in a newborn to cancer in an adult.

Description

Genetic information is contained in DNA (deoxyribonucleic acid). DNA consists of very long strings of building blocks called nucleotides. The nucleotides are paired to form the DNA double helix. Most cells in the human body have about three billion of these nucleotide pairs organized into 23 pairs of chromosomes, with one chromosome of each pair inherited from the mother and one from the father. Genes are the sequences of nucleotides in DNA that contain the instructions for making proteins via mRNAs (messenger ribonucleic acids). There are some 20,000 protein-coding genes in the human genome, accounting for about 1%–2% of the DNA. Other genes code for RNAs that synthesize proteins (ribosomal RNAs and transfer RNAs) or regulate the activities of genes and proteins. Some noncoding DNA regions control the activities of genes. Still, the vast majority of the DNA in the human genome is either extraneous or has as-yet-undiscovered functions.

Every time a cell divides, all of its DNA must be copied (replicated) so that each of the two daughter cells receives a full complement of genomic information. However, in the formation of germline (egg and sperm) cells, the DNA is copied, but each cell gets only one member of each chromosome pair. During fertilization, the chromosomes from the egg and sperm combine so that the cells of the human embryo again have 23 pairs of chromosomes.

Mutations

Mistakes are made during DNA replication. DNA is also damaged by toxins; radiation such as ultraviolet radiation from sunlight; reactive oxygen species that are normal products of metabolism; bacteria, viruses, and other pathogens; and other mechanisms. Fortunately, human cells have excellent mechanisms for repairing replication mistakes and DNA damage and for eliminating cells when the damage cannot be repaired. However, the

KEY TERMS

Aneuploidy—An abnormal number of chromosomes in a cell. Trisomy 18 and trisomy 13 are examples of aneuploid conditions.

Autism spectrum disorder (ASD)—A general term for a group of neurodevelopmental disorders characterized by difficulties in social interactions, significant abnormalities in speech patterns, and limited but repetitive interests and activities.

Copy number variations (CNVs)—Variations within the population in the number of copies of a specific gene.

Down syndrome—A chromosomal disorder caused by the presence of all or part of an extra 21st chromosome.

Exome—The protein-coding portions of the genome.

Gamete—A reproductive cell; an ovum or sperm.

Genome—The entire DNA sequence of a cell or organism.

Germ cell—An egg or sperm cell or the cells that develop into them.

Germline—The cell line from which gametes arise.

Mosaicism—A condition in which an individual's cells are not all genetically identical.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Polymorphism—A change in the base pair sequence of DNA that may or may not be associated with a disease.

Replication—Copying of DNA prior to cell division.

Schizophrenia—A psychotic disorder characterized by loss of contact with one's environment, deterioration of everyday functioning, and personality disintegration.

Single nucleotide polymorphism (SNP)—Single nucleotide variant (SNV); a variation or point mutation in a single nucleotide building block of DNA.

Somatic mutations—*De novo* mutations that are acquired throughout life and affect only some cells in the body.

machinery for correcting or repairing DNA is also prone to errors. If the DNA is not repaired or the cell eliminated, the result is a *de novo* mutation that becomes a permanent part of an individual's genome. However, the mutation is not passed on to offspring unless it is in a germline cell.

There are various types of mutations:

- Single nucleotide polymorphisms (SNPs) or single nucleotide variants (SNVs) are the most common mutations and result from adding the wrong nucleotide, deleting a nucleotide, or adding an extra nucleotide.
- Other common mutations are the deletion or duplication of a region of the DNA. Deletions and duplications range from very short to very long.
- Copy number variants (CNVs) are extra copies of entire genes.
- Chromosome abnormalities are mutations that occur when chromosomes do not segregate correctly into daughter cells. A daughter cell may lack a chromosome or have an extra chromosome, or a piece of a chromosome may have broken off and joined to a different chromosome. For example, Down syndrome (trisomy 21) is a genetic disorder caused by all or part of an extra chromosome 21.

Some mutations, especially SNPs, are very common and occur both within genes and in 1%–4% of noncoding DNA. DNA alterations that are present in more than 1% of the population are called polymorphisms or neutral gene variants. These result in unique individual characteristics, such as eye and hair color and blood type. Other polymorphisms can cause genetic susceptibility to certain diseases and disorders or help protect against them.

Pathogenic mutations that cause genetic disorders are not common in the general population, although they may run in families. These are mutations that change or destroy the functioning of a cell by failing to produce a required protein, producing an abnormal protein, or producing too much of a protein. Such mutations can interfere with development or the functioning of organs or organ systems. Sometimes they are beneficial as well as harmful. For example, inheriting a mutation that produces abnormal hemoglobin—the protein in red blood cells that carries oxygen throughout the body—confers resistance to malaria. However, inheriting two copies of the gene mutation—one from each parent—causes sickle cell disease.

De novo mutations

Evolution proceeds through *de novo* mutations, and all mutations were *de novo* at some point in the ancestral past. Some mutations probably arose anew many times in human populations. However, once a *de novo* mutation enters the germline and is passed down through families, it is considered an inherited rather than a *de novo* mutation. Many, if not most, human disorders and diseases involve inherited or *de novo* mutations that may directly cause a disorder or increase susceptibility to a disease in association with other genetic factors or environmental triggers.

Genetic disorders that do not run in families but rather appear for the first time in an affected individual are caused by *de novo* mutations. These are also called sporadic mutations because they were not inherited from a parent. The mutation may have occurred in a parent's egg or sperm, in the fertilized egg, or in the early embryo. This type of *de novo* mutation will be carried in most or all of the cells of the body. If the mutation is in germline cells, it becomes an inherited mutation that may be passed on to offspring. *De novo* mutations that occur later in development may be carried in only some cells and may or may not be in germline cells. Fortunately, the vast majority of surviving *de novo* mutations are not harmful, either because they do not affect an important region of DNA or because they do not cause the loss of an essential gene or the production of an abnormal protein. However, *de novo* mutations that are lethal to the fetus or prevent fetal development are a frequent cause of miscarriage.

Mosaicism

De novo mutations that occur later in embryonic or fetal development cause mosaicism, in which some cells in the body carry the mutation and others do not—only cells that arose from the mutation-containing cell have the alteration. The specific mutation and the stage of development at which it occurred determine which cells carry the mutation, whether the mutation results in a genetic disorder, and whether it is in the germline and can be passed to offspring. Researchers are discovering that mosaicism is much more common than previously believed.

Acquired (somatic) *de novo* mutations occur throughout life and are present in only some cells of the body. As people age, their cells accumulate more and more *de novo* mutations. A 2015 study reported that these somatic *de novo* mutations may account for up to 6.5% of an individual's genomic variation. Although they are not inherited or passed on to offspring, somatic mutations can cause disease. For example, cancer is caused by multiple *de novo* somatic mutations in just one or a few cells. These mutations enable the cells to grow and divide uncontrollably.

It has been difficult to determine whether a complex genetic disorder was inherited from combinations of multiple genes contributed by the parents, inherited from a mosaic parent without symptoms of the disorder, or caused by a *de novo* mutation. However, this information is important because it indicates whether the parents are likely to conceive another child with the disorder. It is also important for deciding whether other family members should be tested for the mutation. A 2014 study found that among children with disorders presumed to be caused by *de novo* DNA deletions, a small percentage of the parents had the same mutations in some but not all of their cells. Such parents are more likely to have another affected child.

QUESTIONS TO ASK YOUR DOCTOR

- What is the difference between an inherited and a *de novo* mutation?
- What type of mutation caused my child's disorder?
- Could my child's disorder have been due to older parental age?
- Should our family members have genetic testing for the mutation?
- What are the chances that we will have another child with the disorder?

De novo mutation rates

Studies have reported an average *de novo* mutation rate of 1.2×10^{-8} mutations per nucleotide per generation. On average, each person accumulates approximately 74 *de novo* point mutations (SNPs) over the course of a lifetime. Because of *de novo* mutations occurring during development, even identical twins are not born genetically identical. A study that sequenced the entire genomes of two sets of parents and their children found 35 and 40 *de novo* germline point mutations in the children.

It has been estimated that large *de novo* CNVs occur in about 1 in 50 people.

In 2015, researchers from the United States and the Netherlands analyzed 11,000 *de novo* mutations in 250 healthy families and published a map of *de novo* mutation rates for different regions of the human genome. Most were germline mutations. The map revealed regions of the genome that are prone to mutation, with clusters of *de novo* mutations that tended to be caused by a different mechanism than the non-clustered mutations. They further reported that *de novo* mutation rates in the children increased with increasing age of the fathers at the time of conception.

Multiple studies have reported that the rate of *de novo* mutations appears to be higher in people with genetic disorders, especially those with sporadic developmental disorders such as intellectual disability and autism spectrum disorder (ASD). Furthermore, *de novo* mutations that cause CNVs appear to be somewhat higher than *de novo* SNPs. Such studies have also found an association between increased *de novo* mutation rates and paternal age: about two additional mutations for every year of the father's age at the time of conception.

Diseases and disorders

De novo mutations have long been known to cause many genetic disorders. Large-scale *de novo* chromosome abnormalities that are visible under a microscope have been recognized for many decades, and *de novo* CNVs can be detected using a technique called microarrays. However, until recently it was very difficult to study *de novo* point mutations. With the introduction of high-throughput next-generation DNA sequencing technologies, researchers can rapidly sequence whole genomes (all of the DNA in a cell) or all the protein-coding regions of the genome (the exome). This enables them to compare parents and their children to identify *de novo* mutations in the entire genome or exome, and correlate *de novo* point mutations with specific disorders. These new technologies have identified numerous *de novo* point mutations that cause sporadic cases of rare genetic disorders. Nevertheless, because of the large number of *de novo* mutations per generation, it remains difficult to identify *de novo* point mutations that contribute to or are responsible for a particular disorder.

Examples of *de novo* mutations that have been linked to rare genetic disorders include mutations in the following:

- *SETBP1* gene encoding SET binding protein 1, which causes Schinzel-Giedion syndrome characterized by intellectual disability and neurodegeneration
- *MLL2* (mixed-lineage leukemia 2) gene, which causes Kabuki syndrome characterized by congenital abnormalities and intellectual disability
- *ASXL1* (additional sex-like combs) gene, which causes Bohring-Opitz syndrome with severe intellectual disability and birth defects
- *ANKRD11* (ankyrin repeat domain 11) gene, which causes KBG syndrome with facial and skeletal malformations and developmental delays
- *CHD7* (chromodomain helicase DNA binding protein 7) gene, which causes CHARGE syndrome with heart defects, other birth defects, and breathing problems
- *ACTB/ACTG1* (actin beta/actin gamma 1) gene, which causes brain malformation in Baraitser-Winter syndrome
- *AKT1* (V-akt murine thymoma viral oncogene homolog 1) gene, which causes Proteus syndrome with abnormal bone development and skin overgrowth

While most *de novo* mutations are harmless, they tend to be more damaging than inherited mutations or variations, presumably because they have not undergone evolutionary selection. *De novo* mutations that have been associated with sporadic disorders tend to be highly damaging. They often affect genes that are important for development, especially neurodevelopment. Multiple studies have reported links

between *de novo* mutations—both point mutations and CNVs—and ASD, schizophrenia, and intellectual disabilities. A 2014 study found some of the same *de novo* mutations in ASD and schizophrenia. These mutations affected proteins that are important for brain functioning. Furthermore, the number of *de novo* mutations in individuals with intellectual disabilities appears to correlate with the severity of symptoms.

By sequencing the genomes of sperm and comparing them to the germline sequences, researchers can identify *de novo* mutations that have occurred in individual sperm cells. It has long been known that *de novo* aneuploidy (variations in chromosome number) most often occurs in older egg cells and that the risk of Down syndrome and other *de novo* aneuploidies increases with increasing maternal age. It now appears that increasing paternal age increases the risk of several common neurodevelopmental disorders such as schizophrenia and ASD. It has been suggested that there is an association between the dramatic increase in ASD diagnoses and an ongoing trend toward older paternity, and that this association is related to an increase in *de novo* mutations in older sperm.

Dementia, hereditary forms

Definition

Dementia is a syndrome (group of symptoms) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with the tasks of daily life. There are many types of dementia, including forms that are inherited. Alzheimer's disease (AD)—by far the most common type of dementia—can be caused by inheriting specific variants (alleles) of certain genes. Inherited variants or mutations (changes) in certain other genes increase the risk of developing AD.

Description

Dementia is characterized by memory loss and an overall decline in intellectual functioning, including difficulties with language, simple calculations, planning, and judgment and motor (muscular movement) skills. Although dementia is not caused by aging, it most often affects older people. Signs and symptoms occur as nerve cells (neurons) in the brain stop functioning, lose connections with other neurons, and begin to die.

Dementia can be caused by some 40 different diseases and conditions, many of which are at least partially inherited. Some gene variants increase susceptibility to certain types of dementia. Other dementias may have underlying genetic causes that have not yet been identified.

- Primary dementia is characterized by damage to or wasting away of the brain tissue itself, in the absence of other disorders. Primary dementias include AD and frontotemporal disorders (FTD) that mainly affect the frontal and temporal lobes of the brain. Frontotemporal dementia with Parkinsonism linked to chromosome 17 (FTDP-17) is a rare type of inherited dementia.
- Vascular dementia (VaD) is caused by blood clots in small blood vessels of the brain. When the clots cut off blood supply to the brain tissue, the brain cells are damaged and may die. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an inherited type of VaD.
- Lewy body dementia (LBD), which includes dementia associated with Parkinson's disease, is characterized by protein aggregates called Lewy bodies that form inside nerve cells in the brain.
- Creutzfeldt-Jakob disease (CJD) is caused by infectious abnormal proteins, but some forms appear to have a genetic basis.
- Huntington's disease is caused by excessive repeats of a specific DNA sequence in the gene encoding a protein

called huntingtin. Huntington's disease is characterized by abnormal, uncontrolled movements and dementia, usually beginning between the ages of 30 and 40. It is an autosomal dominant trait, which means that the children of a parent with Huntington's disease have a 50% risk of developing the disorder.

Although most dementias, especially those that are at least partially inherited, are progressive neurodegenerative diseases that ultimately end in death, some dementias—especially those caused by outside agents such as heavy metals, alcoholism, overuse of certain drugs, or infectious diseases—may be reversible. In addition to heredity and environmental factors, dementias can be caused by abnormalities in the structure of the brain, tumors, brain trauma or injury, blood collecting beneath the membrane that covers the brain (subdural hematoma), depression, thyroid dysfunction, and niacin or vitamin B₁₂ deficiency.

AD, FTD, and certain rarer types of dementia are characterized by abnormal clumps called beta-amyloid plaques and bundles of fibers called neurofibrillary tangles. The plaques are sticky clumps or clusters of dead and dying neurons and other cellular debris surrounding insoluble deposits of beta-amyloid. The latter are fragments of a larger protein called amyloid precursor protein (APP) that has not been properly processed. These plaques are situated between neurons and are believed to

interfere with normal communication between neurons, eventually causing the nerve cells to die. Neurofibrillary tangles are accumulations of twisted fragments of tau proteins inside neurons. Tau proteins normally bind and stabilize neurons. When tau proteins are damaged by the addition of phosphate, a process called hyperphosphorylation, they form filaments that twist around each other to form neurofibrillary tangles that can no longer stabilize the neurons. Increased beta-amyloid may cause the formation of neurofibrillary tangles; however, it is not known whether the plaques and tangles cause AD and other dementias or are the result of them. Plaques and tangles occur as part of the normal aging process but are far less prevalent in normal brains. As increasing numbers of neurons die and nerve cell connections are disrupted, areas of the brain that are essential for memory and learning are destroyed, followed by areas responsible for language and reasoning. Eventually many areas of the brain atrophy (become shrunken and dysfunctional).

Genetic profile

AD is believed to most often be caused by a combination of genetic and environmental factors. Most cases of AD are late-onset, developing after ages 60–65, and more than 75% of patients have no family history of the disease. About 25% of AD cases are familial, with patients having family histories of AD. They may have inherited AD susceptibility or risk genes from their parents and/or share environmental or lifestyle risk factors with family members. Familial AD may be either early-onset or late-onset. Many other dementias share genetic factors, as well as symptoms, with AD. AD, FTD, VaD, and LBD—the four most common types of dementia—all involve genes associated with abnormal tau protein and/or brain inflammation. AD, VaD, and LBD are all thought to involve genes that produce amyloid protein. LBD and dementia associated with Parkinson's disease are believed to involve genes associated with alpha-synuclein, a protein that aggregates in Lewy bodies.

Early-onset AD

Early-onset AD develops between the ages of 30 and 60 and can be caused by inheriting one of three defective genes. Variant alleles or mutations in any of these three genes result in the production of abnormal proteins that can directly cause familial early-onset AD. Because these genes are located on chromosomes other than the X and Y sex chromosomes, they are called autosomal genes and affect males and females with equal frequency. A defective version of one of these genes, inherited from one parent, can cause AD even if a normal version of the same gene is inherited from the other parent. Therefore, the defective gene is described as dominant, and AD

caused by one of these defective genes is known as autosomal dominant Alzheimer's disease (ADAD). Each child of a parent with one of these defective genes has a 50% risk of inheriting the gene and AD. If both parents have one copy of the mutant gene, each of their children has a 75% chance of inheriting at least one copy of the gene. Parents carrying two copies of the mutant gene will pass on the defective gene to all of their offspring.

All three of the abnormal proteins produced by these early-onset AD genes increase the amount of beta-amyloid in the brain.

- Mutations in the *APP* gene, located on chromosome 21, are associated with AD onset between the ages of 55 and 60, which is sometimes called AD1.
- Variations or mutations in the presenilin-1 (*PS-1*) gene on chromosome 14 are the most common cause of early-onset AD, sometimes referred to as AD3. PS-1 may be one of the enzymes that cuts APP into beta-amyloid. It also may be important for the functioning of synaptic connections between neurons.
- AD4 is an extremely rare genetic defect in the presenilin-2 (*PS-2*) gene located on chromosome 1. Presenilin 2 is involved in processing APP.

AD-causing mutations in these “deterministic” genes are very rare, accounting for less than 5% of AD cases. They do not appear to be involved in late-onset AD. Since mutations in these genes account for only about 50% of early-onset familial AD, there are presumed to be other as-yet-unidentified genes associated with early-onset AD.

Early-onset AD is also associated with Down syndrome—a genetic disorder caused by the presence of part or all of an extra chromosome 21. People over age 40 with Down syndrome develop the brain changes characteristic of AD. This is thought to be due to the overproduction of APP caused by the *APP* gene on the extra chromosome 21. Down syndrome-associated AD accounts for less than 1% of all AD cases.

Late-onset AD

As of 2021, 25 different genes had been associated with late-onset AD. It is expected that many more associated genes will be identified in the future. The presence of specific versions of these genes or mutations in these genes may increase the risk of late-onset AD.

The gene with the strongest influence on AD is the apolipoprotein E (*APOE*) gene located on chromosome 19. Familial late-onset AD associated with the *APOE* gene is sometimes called AD2. The *APOE* gene codes for a protein that helps remove cholesterol from the blood. There are three common versions of *APOE*:

APOE-2, *APOE-3*, and *APOE-4*. *APOE-2*, which is relatively rare, may provide some protection against AD. *APOE-3*, the most common *APOE* variant, does not appear to affect AD risk. *APOE-4* occurs in 10%–15% of the population and in 40%–60% of all people with late-onset AD. People who inherit an *APOE-4* gene from one parent are at increased risk for AD; those who inherit two copies of *APOE-4*—one from each parent—are at higher risk for AD. *APOE-4* may also cause AD at a younger-than-average age. Nevertheless, many people with one or two copies of *APOE-4* do not develop AD, and many people with AD do not have an *APOE-4* gene.

Other genes with variant alleles that have been associated with AD risk include the following:

- *BINI*, which encodes a protein that interacts with tau protein
- *CLU*, which helps regulate clearance of beta-amyloid from the brain
- *PICALM*, which is involved in communication between neurons
- *SORL1*, which is involved in regulating the transport of APP and lipoproteins
- *CRI*, which encodes a protein that, when deficient, may contribute to chronic inflammation in the brain, which may be a factor in AD
- *TREM2*, which is involved in regulation of the response to inflammation in the brain

Frontotemporal disorders

Frontotemporal disorders account for up to 10% of all dementias. Tau aggregates are present in some FTD cases and are associated with mutations in the *MAPT* (“microtubule-associated protein tau”) gene that produces tau protein. Other types of FTD exhibit aggregates of a protein called TDP-43. Abnormal TDP-43 protein is found in people with an inherited form of amyotrophic lateral sclerosis (ALS), a motor neuron disease that may be accompanied by frontotemporal dementia. Mutations affecting the protein progranulin may also be involved in some cases of TDP-43-related FTD. Yet another FTD that runs in families is associated with a variant of the *TREM2* gene. FTDP-17 is a rare form of dementia that is believed to be caused by an autosomal dominant mutation in a *MAPT* gene that is inherited from one parent. A mutation in the *TREM2* gene is common in people with a very-early-onset FTD that occurs in some Turkish families.

Vascular dementia

Although most cases of VaD are related to high blood pressure and other vascular problems, CADASIL is an

early-onset, autosomal dominant dementia inherited from one parent. It is caused by mutations in the *NOTCH3* gene that thickens the walls of small and medium blood vessels, slowing blood flow to the brain.

Creutzfeldt-Jakob disease

Although CJD is caused by an infectious protein called a prion, researchers believe that 5%–15% of cases may have a genetic component. These include Gerstmann-Sträussler-Scheinker disease and fatal familial insomnia, which is characterized by degeneration of areas of the brain that are important for sleep.

Demographics

It is estimated that more than 15% of North Americans older than age 65—and 40% of those older than 80—have dementia. However, it can be difficult to determine the specific type of dementia, and many people may have more than one type.

AD, the most common cause of dementia in the elderly, accounts for 50%–70% of dementias and 75% in people over age 65. As of 2021, an estimated 6.5 million Americans were living with AD—6.2 million of them aged 65 and older. In 2014, AD was an underlying cause of death for an estimated 700,000 Americans aged 65 and over. If current trends in AD incidence and life expectancy continue, it is estimated that by 2050, 12.7 million Americans aged 65 and over will have AD. Although two-thirds of Americans with AD are female, this is generally attributed to their longer life expectancy. African Americans and Latino Americans have higher rates of both AD and vascular disease than other racial and ethnic groups.

The incidence of AD in other developed countries with aging populations is similar to that in the United States. The risk of AD doubles every five years after age 65, to almost 50% in people over 85. Furthermore, AD is both underdiagnosed and misdiagnosed, at least until its later stages. It is estimated that at least half of affected people are unaware of their disease.

Signs and symptoms

Common symptoms of dementia include the following:

- Weakening of the memory with regard to learning new information as well as recalling previously learned information
- Aphasia or the loss of language function, including the frequent use of vague words such as “it” or “thing,” echoing what others say, repeating words or phrases over

and over, or not speaking at all in the later stages of dementia

- Apraxia or loss of the ability to perform intentional movements, such as brushing one's teeth or tying one's shoelaces
- Agnosia or loss of the ability to recognize objects or even family members or one's own face reflected in a mirror
- Problems with abstract thinking and complex behavior and loss of the ability to plan, carry out the steps of a task in the proper order, make appropriate decisions, evaluate situations, or show good judgment, such as lighting a stove burner with nothing in the pan or being unable to record checks and balance a checkbook.

The following sections focus on signs and symptoms that can differentiate among the various types of dementia.

Alzheimer disease

Dementia related to AD often progresses slowly, but at different rates in different people. In early stages, short-term memory loss may be accompanied by irritability, wide mood swings, and personality changes. In second-stage AD, the patient typically gets easily lost, is disoriented with regard to time and space, and may become angry, uncooperative, or aggressive. Language difficulties develop, and daily tasks may become difficult. Late-stage AD patients require constant supervision. Those who can rise from bed may wander aimlessly, although muscle stiffening may make walking difficult. Patients are often unable to reason or demonstrate appropriate judgment. They may become uninhibited and confrontational. They may experience delusions or hallucinations. In final-stage AD, patients are completely bedridden, have lost control over bowel and bladder functions, and may be unable to eat or swallow. The risk of seizures increases. Death usually results from an infection or malnutrition.

Frontotemporal dementia

Frontal lobe dementias are gradual in onset. The first symptoms often include socially inappropriate behavior (rude remarks, sexual acting-out, and poor personal hygiene). Patients are often obsessed with eating and may put nonfood items in their mouths, as well as make frequent sucking or smacking noises. In the later stages, the patient may develop muscle weakness, twitching, and delusions or hallucinations.

Vascular dementia

In early-stage VaD, patients tend to retain their personality more fully than with AD. This type of dementia often progresses in a stepwise fashion; that is, the patient shows rapid changes in functioning, and then remains at a plateau for a time rather than showing a

continuous decline. The symptoms may also have a "patchy" quality; that is, some of the patient's mental functions may be severely affected, whereas others are relatively undamaged. Other symptoms can include exaggerated reflexes, an abnormal gait (manner of walking), loss of bladder or bowel control, and inappropriate laughing or crying. CADASIL can first appear in people as young as 20–40.

Lewy body dementia

LBD may combine some features of AD, such as severe memory loss and confusion, with certain symptoms associated with Parkinson's disease, including stiff muscles, a shuffling gait, and trembling or shaking of the hands. Visual hallucinations may be one of the first symptoms of LBD.

Creutzfeldt-Jakob disease

CJD occurs most often in people between the ages of 40 and 60. It is typically preceded by a period of several weeks in which the patient complains of unusual tiredness, anxiety, loss of appetite, or difficulty concentrating. This type of dementia generally progresses much more rapidly than other dementias, usually over a span of a few months.

Diagnosis

Dementia may be diagnosed by a patient's primary physician; in many instances, however, the patient will be referred to a neurologist or a specialist in geriatric medicine. The differential diagnosis of dementia is complicated because of the multiple possible causes, because more than one cause may be present, and because dementia can coexist with other conditions such as depression or delirium. Delirium is a temporary disturbance of consciousness marked by confusion, restlessness, inability to focus one's attention, hallucinations, or delusions. In elderly people, delirium is frequently a side effect of surgery, medications, infectious illnesses, or dehydration. Delirium can be distinguished from dementia because delirium usually comes on fairly suddenly (in a few hours or days) and may vary in severity—it is often worse at night. Dementia develops much more slowly, over a period of months or years, and the patient's symptoms are relatively stable. It is possible to have delirium and dementia at the same time. It is also important to distinguish between dementia and age-associated memory impairment (AAMI). Older people with AAMI have a mild degree of memory loss, they do not learn new information as quickly as younger people, and they may take longer to recall a certain fact or to balance their checkbook. However, they do not suffer the degree of memory impairment that characterizes dementia, and they do not get progressively worse.

KEY TERMS

Age-associated memory impairment (AAMI)—A condition in which an older person suffers some memory loss and takes longer to learn new information; AAMI is distinguished from dementia in that it is not progressive and does not represent a serious decline from the person's previous level of functioning.

Agnosia—Loss of the ability to recognize objects by use of the physical senses.

Allele—Any of the alternative versions of a gene that are present in the population.

Alpha-synuclein—A protein that forms aggregates in nerve cells in certain types of dementia.

Alzheimer's disease (AD)—A progressive neurodegenerative disease characterized by loss of function and death of nerve cells in several areas of the brain, leading to mental deterioration; the most common cause of dementia.

Amyloid precursor protein (APP)—A protein that forms beta-amyloid in the brain when it is not properly broken down; mutations in the *APP* gene can cause early-onset familial Alzheimer's disease.

Aphasia—Loss of previously acquired ability to speak or understand written or spoken language.

Apolipoprotein E (APOE)—A protein that transports cholesterol and helps remove it from the bloodstream; the gene encoding one form of this protein, *APOE-4*, is associated with an increased risk of late-onset Alzheimer's disease.

Apraxia—Impairment of the ability to make purposeful movements without paralysis or loss of sensation.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Beta-amyloid plaques—Dead or dying nerve cells and cell debris surrounding deposits of beta-amyloid protein in the brain; excess plaques are diagnostic of Alzheimer's disease.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL)—An inherited type of vascular dementia.

Creutzfeldt-Jakob disease (CJD)—A degenerative disease of the central nervous system caused by an abnormal protein called a prion.

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness; it can be distinguished from dementia by its relatively sudden onset and variation in the severity of the symptoms.

Frontotemporal disorders (FTD)—Various types of dementia that affect the frontal and temporal lobes of the brain; FTDP-17 is a rare inherited FTD.

Hematoma—An accumulation of blood, often clotted, in a body tissue or organ, usually caused by a break or tear in a blood vessel.

Huntington's disease—A midlife-onset inherited disorder characterized by progressive dementia and loss of control over voluntary movements.

Lewy body dementia (LBD)—A common progressive form of dementia in which protein aggregates called Lewy bodies form in neurons.

Mental status examination (MSE)—An evaluation of the ability to communicate, follow instructions, recall information, and complete movement and coordination tasks, as well as emotional state and general sense of space and time.

Neurofibrillary tangles—Accumulations of twisted tau protein fragments inside nerve cells in the brain that are diagnostic of Alzheimer's disease.

Parkinson's disease—A nervous system disease, most common in people over 60, and characterized by a shuffling gait, trembling of the fingers and hands, muscle stiffness, and possibly dementia.

Presenilins (PS-1; PS-2)—Proteins involved in processing amyloid precursor protein; mutations in the genes encoding these proteins can cause early-onset familial Alzheimer's disease.

Tau—A protein involved in maintaining the internal structure of nerve cells; tau is damaged in Alzheimer's disease and forms neurofibrillary tangles.

Vascular dementias (VaD)—Dementias caused by damage to blood vessels in the brain.

Although skilled physicians can diagnose probable AD with 90% accuracy, a definitive diagnosis is only possible by examination of brain tissue after death. Beta-amyloid plaques and intraneuronal neurofibrillary

tangles normally occur with age but are greatly increased in AD. The plaques and tangles are similar regardless of whether the AD is sporadic, familial early-onset, familial late-onset, or Down syndrome-related. The

further the disease has progressed, the smaller the brain at death.

Patient history

The doctor will begin by taking a full history, including the patient's medical history, occupation, and educational level. The occupational and educational history allows the examiner to make a more accurate assessment of the extent of the patient's memory loss and other evidence of intellectual decline. In some cases, occupational history may indicate exposure to heavy metals or other toxins. A complete medical history allows the doctor to assess possibilities such as delirium, depression, alcohol-related dementia, dementia related to head injury, or dementia caused by infection. It is particularly important for the doctor to have a list of all the patient's medications, including over-the-counter preparations, because of the possibility that the patient's symptoms are related to drug side effects.

Mental status examination

A mental status examination (MSE) evaluates the patient's ability to communicate, follow instructions, recall information, and perform simple tasks involving movement and coordination, as well as emotional state and general sense of space and time. The MSE includes the doctor's informal evaluation of the patient's appearance, vocal tone, facial expressions, posture, and gait, as well as formal questions and instructions. A common form that has been used since 1975 is the Folstein Mini-Mental Status Examination or MMSE. Questions that are relevant to diagnosing dementia include asking the patient to count backward from 100 by 7s, to make change, to name the current president, to repeat a short phrase after the examiner, to draw a clock face or geometric figure, and to follow a set of instructions involving movement (e.g., "Show me how to throw a ball" or "Fold this piece of paper and place it under the lamp on the bookshelf"). The examiner may test abstract reasoning ability by asking the patient to explain a familiar proverb or test judgment by asking about a problem with a common-sense solution, such as what one does when a prescription runs out.

Neurologic examination

A neurologic examination includes an evaluation of the patient's cranial nerves and reflexes. The cranial nerves govern the ability to speak as well as sight, hearing, taste, and smell. The patient will be asked to stick out the tongue, follow the examiner's finger with the eyes, raise the eyebrows, and so on. The patient is also asked to perform certain actions (e.g., touching the nose with the eyes closed) that test coordination and spatial orientation.

QUESTIONS TO ASK YOUR DOCTOR

- How is early dementia distinguished from normal age-associated memory impairment?
- What types of dementia am I at risk for?
- Should I have genetic testing for dementia risk genes?
- Should my family members undergo genetic testing?
- Are there other tests for hereditary dementia?
- Are there treatments for hereditary forms of dementia?

The doctor will usually touch or tap certain areas of the body, such as the knee or sole of the foot, to test the patient's reflexes. Failure to respond to the touch or tap may indicate damage to certain parts of the brain.

Laboratory tests

Blood and urine samples are collected to rule out causes of dementia such as thyroid deficiency, vitamin deficiency, heavy metal poisoning, liver disease, HIV infection, syphilis, anemia, medication reactions, or kidney failure. A lumbar puncture (spinal tap) may be done to rule out neurosyphilis.

Diagnostic imaging

A CT (computed tomography) scan or MRI (magnetic resonance imaging) may be used to detect evidence of strokes, disintegration of the brain tissue in certain areas, blood clots or tumors, a buildup of spinal fluid, or bleeding into the brain tissue. PET (positron-emission tomography) or SPECT (single photon emission computed tomography) imaging is not used routinely to diagnose dementia, but it may be used to rule out AD or FTD if a patient's CT scan or MRI is unrevealing.

Genetic testing

Genetic testing is available for some genes associated with dementia, including early-onset AD genes, *APOE*, and *NOTCH3*, which causes CADASIL. Most experts do not recommend *APOE* gene testing because people with *APOE-4* do not necessarily develop AD and people without *APOE-4* may develop the disease. Furthermore, there is no preventive or effective treatment for AD. In some cases, genetic testing for early-onset AD may be

appropriate; for example, for advanced planning or for diagnosis and ruling out other causes of the symptoms.

Treatment and management

Most dementias, including hereditary forms, are irreversible. There are no “magic bullets” that can slow or stop the progression of dementias such as AD, FTD, VaD, or LBD. Medications can ease symptoms such as depression, anxiety, sleep disturbances, and psychosis. Dementia patients are more susceptible to the side effects of medications, especially psychoactive drugs, and are usually given lower doses. Physicians often recommend first trying to reduce behavioral symptoms with changes to the patient’s environment. LBD appears to respond better to treatment with newer antipsychotic medications than to treatment with older drugs such as haloperidol (Haldol). Cholinesterase inhibitors—galantamine, rivastigmine, and donepezil—are prescribed for mild-to-moderate AD and may delay some symptoms or prevent them from worsening for a limited time. They may also help control some behavioral symptoms. Acetylcholine is a neurotransmitter that is important for memory and thinking. Cholinesterase inhibitors increase the amount of acetylcholine in the brain by preventing its breakdown. However, as AD progresses, the brain produces less and less acetylcholine, and the drugs become ineffective. Memantine is an N-methyl D-aspartate (NMDA) antagonist that lowers the amount of glutamate in the brain, since excess glutamate can cause brain cell death. Memantine is used to delay the progression of some symptoms of moderate-to-severe AD. It may help patients maintain some activities such as toileting for a bit longer. However, all of these drugs are ineffective for many patients.

Patients in the early stages of dementia can often remain at home with help from family members or other caregivers, especially if the home can be fitted with safety features (handrails, good lighting, locks for cabinets containing dangerous products, nonslip treads on stairs, etc.). Patients in the later stages of dementia usually require skilled care in a nursing home or hospital.

Prognosis

Most common dementias, including hereditary forms, progress with a gradual deterioration in functioning. Although there is considerable variation in the rate of disease progression, symptoms continue to worsen, usually over a period of years. Eventually, loss of brain cells and brain damage result in the impairment of autonomic body functions, the failure of various organ systems, coma, and death. Most AD patients die within 8–10 years of diagnosis, although survival can be as

short as one year or as long as 20 years. The life expectancy of AD patients is increasing because the disease is generally being diagnosed at an earlier stage. Infection is the most common direct cause of death in AD patients. People with AD are often in poor health and may be malnourished, which puts them at increased risk for life-threatening infections such as pneumonia. They are also susceptible to other conditions and diseases of old age. The consequences of cancer, stroke, and heart disease can be more severe in patients with AD than in otherwise healthy people.

Dent disease

Definition

Dent disease is a rare X-linked recessive genetic disease that adversely affects the kidneys of male patients. First described in 1964 by Charles Enrique Dent (1911–1976), a British physician, and his colleague M. Friedman, the disease is marked by dysfunction of the proximal tubules of the kidney. As of 2021, Dent disease was classified in two forms: Dent disease 1, with symptoms primarily related to kidney function; and Dent disease 2, with additional symptoms that include mild intellectual disability, poor muscle tone (hypotonia), and eye problems. Dent disease 1 is the more common of the two forms.

Description

A renal tubular disorder, Dent disease causes elevated levels of calcium in the urine, low levels of phosphorus in the blood, leakage of small proteins into the urine, weak bones, renal dysfunction, and kidney calcification. Consequently, the disorder causes damage to the proximal tubules of the kidneys (the portion of the duct system of the nephron leading from Bowman's capsule to the loop of Henle). Such damage eventually results in progressive kidney dysfunction (the inability of the kidneys to excrete the products of metabolism from the blood) and ultimately to kidney failure.

Patients with Dent disease 1 may experience such symptoms of the disease as abdominal cramps, bloody urine (hematuria), kidney stone formation, pain on passage of the kidney stones, bone pain, and weakening of the bones in early childhood; or they may have mild symptoms that are not correctly diagnosed until the early adult years. In many cases of Dent disease 1, progressive loss of kidney function leads to end-stage renal disease (ESRD) by the middle adult years (30s to 50s).

Patients with Dent disease 2 typically have mild visual disturbances, low muscle tone, and a risk of intellectual disability in addition to the progressive kidney insufficiency and abnormal laboratory findings (particularly hypercalciuria) characteristic of Dent disease 1.

Genetic profile

Dent disease is inherited in an X-linked recessive pattern; both genes associated with the disorder are located on the X chromosome, which means that a male inheriting a defective gene from his mother will manifest the disorder because he lacks a second X chromosome with a normal gene. A female inheriting a mutated gene for Dent disease will be a carrier but will not develop symptoms of the disorder herself.

The gene responsible for Dent disease 1 is *CLCN5*, which encodes a kidney-specific voltage-gated chloride channel. The other gene, which is responsible for Dent disease 2, is *OCRL* (also called *OCRL1*; short for oculocerebrorenal syndrome of Lowe), which encodes a phosphatidylinositol 4,5-bisphosphate (PIP2) 5-phosphatase. Some researchers think that Dent disease 2 may be a mild variant of Lowe syndrome, which is also caused by mutations in the *OCRL* gene, and which is also characterized by kidney dysfunction and visual impairments. The major difference between Dent disease 2 and Lowe syndrome is the presence of behavioral disorders, an increased risk of epilepsy, and mild to severe intellectual impairment in the latter.

In 60% of cases, Dent disease is caused by inactivating mutations in the *CLCN5* gene. *CLCN5* is a member of the chloride channel (CLC) family of chloride ion channels and ion transporters (*CLCN1*–*CLCN7*, and *CLCKa* and *CLCKb*). These CLCs play important roles in the control of volume, migration, proliferation, and differentiation of cells, along with the regulation of acidity levels. *CLCN5* is located on the short arm of the X chromosome at Xp11.22; has a coding sequence of 2238-bp, which consists of 12 exons that span approximately 30 kilobases of genomic DNA (deoxyribonucleic acid); and encodes a 746 amino acid protein (CLC-5).

In 15% of cases, the disorder is associated with mutations in the *OCRL* gene, located on the long arm of the X chromosome at Xq25. In the remaining 25% of cases, the genetic cause of the disorder was unknown as of 2021.

Demographics

Dent disease is an extremely rare disorder. About 250 cases of Dent disease 1 and 25 cases of Dent disease 2 have been reported in the medical literature since the disorder was identified in 1964. One estimate is that Dent disease affects one male in every 500,000. It is thought that the disease may be underdiagnosed because its symptoms are similar to those of other kidney disorders and because some patients have relatively mild symptoms.

As far as is known, Dent disease appears in all races and ethnic groups worldwide. It is possible, however, that symptom profiles may vary somewhat between Western and Asian populations. A group of Japanese researchers reported in 2014 that their patients diagnosed with Dent 2 as well as Dent 1 disease showed a wider range of symptom severity than their counterparts in European and American case reports.

Signs and symptoms

Symptoms in males may appear at any time from early childhood through the early adult years. Early

KEY TERMS

End-stage renal disease (ESRD)—A potentially fatal condition that occurs when the kidneys can no longer effectively filter urine and excrete waste products from the body.

Hypercalciuria—Abnormally high levels of calcium in the urine.

Idiopathic—Referring to a disease of unknown origin or arising spontaneously.

Ion channel—A transmembrane protein that transports ions across a plasma membrane in the direction of their concentration (electrochemical) gradient; also called ion pump.

Ion transporter—A transmembrane protein that transports ions across a plasma membrane against the direction of their concentration (electrochemical) gradient.

Kidneys—A pair of body organs whose primary function is to produce urine.

Lowe syndrome—A rare X-linked recessive disorder characterized by congenital eye disorders as well as renal tubular dysfunction, and caused by mutations in the same gene as Dent disease 2.

Nephrocalcinosis—An abnormal increase in calcium levels in kidney tissue.

Nephrolithiasis—The medical term for the process of kidney stone formation.

Osteomalacia—The medical term for bone softening in adults due to inadequate levels of dietary calcium or phosphate, or the resorption of calcium from the

bones by excessive secretion of parathyroid hormone.

Peritoneal dialysis—A form of therapy for kidney disorders that involves using the patient's abdomen (peritoneal cavity) as the site of treatment. Fluid is infused into the abdomen through a catheter and remains in the abdomen for several hours while waste products diffuse into the fluid from the abdominal blood vessels. The fluid is then removed and replaced with fresh fluid four to six times per day.

Renal—Relating to or affecting the kidneys.

Renal calculus (plural, calculi)—The medical term for a kidney stone. Kidney stones are formed from minerals dissolved in the urine.

Renal tubular disorders—Various defects in the renal tubular transport processes and their regulation.

Rickets—Defective calcification or mineralization of bones in children due to lack of vitamin D in the diet, defective metabolism of vitamin D, or insufficient calcium in the diet. The equivalent condition in adults is called osteomalacia.

Serum—The liquid part of blood.

Voltage-gated calcium channel—A type of voltage-gated (voltage-dependent) ion channel found in excitable cells (such as muscles, neurons) that are permeable to the calcium ion.

X-linked disorder—Any disorder caused by genes located on the X chromosome.

symptoms of Dent disease are similar to the indicators of rickets or calculi (stones that form in an organ or duct). In the more serious cases of Dent disease, kidney dysfunction can be an early symptom.

Although females only carry the disease rather than developing the full-blown syndrome, they may have abnormal test results on laboratory urine tests. Female carriers of Dent disease do not, however, develop kidney stones or kidney dysfunction.

The most common clinical features of the disorder in males include the following:

- **Proteinuria:** High serum proteins are present in the urine. Half the cases also result in low-molecular-weight (LMW) proteins.
- **Aminoaciduria:** Elevated levels of amino acids appear in the urine.

- **Glycosuria:** Also called glucosuria, high levels of glucose are present in excreted urine.
- **Kaliuresis:** High levels of potassium are present in excreted urine.
- **Hyperuricosuria:** Excessive levels of uric acid are present in the urine. Impaired urinary acidification: Inability to secrete acidic urine occurs.
- **Hypercalciuria:** Modest amounts of calcium are present in the urine.
- **Serum calcium:** Normal levels of calcium are present in the blood.
- **Oxalate and citrate:** Urinary oxalate and citrate levels are normal.
- **Hypophosphatemia:** Low levels of phosphorus appear in the blood.

- Low levels of parathyroid hormone (PTH) are present.
- Vitamin D: Increased levels of 1,25 vitamin D are present; medically known as calcitriol (1,25-Dihydroxycholecalciferol), which is the active form of vitamin D found in the body.
- Nephrocalcinosis: Deposits of calcium may accumulate in kidney tissue.
- Calcium nephrolithiasis: Kidney stones composed of calcium oxalate, calcium phosphate, or both, are present in about half of patients with Dent disease. The stones form from minerals dissolved in the urine.
- Osteomalacia: Indications of weak bones are present in adults with the disorder.
- Rickets: Inadequate mineralization of bones in children, which can result in fractures and limb deformities.
- Thirst. Constant and excessive thirst is often exhibited, along with frequent urination. Dehydration often results.
- Loss of appetite and unintended weight loss.

Diagnosis

Because it occurs only rarely, Dent disease is often misdiagnosed as idiopathic hypercalciuria (IH), an excess of urinary calcium without any obvious cause. It can, however, be diagnosed definitively by a combination of laboratory tests and molecular genetic testing.

Examination

During an office examination, young patients may be suspected of having Dent disease on the basis of clinical symptoms, particularly short stature, frequent urination, dehydration, anemia, fatigue, loss of appetite, weight loss, and weakened and/or painful bones and joints.

Laboratory tests

Numerous laboratory tests can be performed to help diagnose Dent disease. For instance, if the disease is present, then serum proteins in the urine will range from one to two grams per day, with the probability that low-molecular weight proteins of less than 30,000 daltons are also present. In addition, elevated levels of amino acids, glucose, potassium, and uric acid are likely to be present in the urine. The urine will often have relatively low acidity. In addition, calcium levels in the urine will range from four to six milligrams per kilogram body weight (while at the same time kidney function and serum calcium levels are normal). Oxalate and citrate levels should appear normal in the urine. However, low levels of parathyroid hormone (PTH) are present, while increased levels of vitamin D should be found.

The appearance of low-molecular-weight proteins in the urine is identified by measuring levels of two

common proteins: α 1 microglobulin and retinol binding protein.

Genetic testing

Genetic testing is often performed to identify gene mutations that are specific to Dent disease. Patients are tested for mutations within the genes *CLCN5* (Dent disease 1) and *OCRL* (Dent disease 2). Molecular testing for mutations in both genes is readily available. When a person is diagnosed with Dent disease on the basis of genetic testing, such testing may be recommended for other family members following consultation with a genetic counselor.

Treatment and management

Because the mechanisms that cause kidney scarring and eventual kidney failure are poorly understood, the treatment for Dent disease is primarily supportive, limited to reducing damage to kidney tissue and preventing or at least minimizing kidney failure. There were no standard guidelines for therapy as of 2021 because the disease was so rare that a sufficiently large sample of patients could not be recruited for clinical trials.

Reducing levels of calcium in the urine is one goal of therapy because high calcium levels are assumed to cause kidney stones and kidney calcification. Because nephrolithiasis (the formation of kidney stones) and nephrocalcinosis (calcification of kidney tissue) appear to be related to hypercalciuria (high levels of urinary calcium), treatment typically includes a thiazide diuretic (such as hydrochlorothiazide, commonly abbreviated HCTZ) to stimulate renal calcium reabsorption and reduce the amount of calcium excreted in urine. In some cases, this treatment works. However, little data have been collected as to whether thiazide diuretics reduce the numbers of kidney stones or minimize kidney problems. In addition, the use of thiazide diuretics is known to cause low levels of potassium in the blood (hypokalemia).

For osteomalacia (weak bones), vitamin D or related derivative compounds can increase bone strength. However, the use of vitamin D must be carefully monitored because its use increases the risk of high levels of urinary calcium.

For idiopathic hypercalciuria, the potassium-sparing diuretic amiloride is used. This drug increases distal tubular calcium reabsorption.

Patients with ESRD may benefit from hemodialysis, peritoneal dialysis, or kidney transplantation. Peritoneal dialysis is less efficient than hemodialysis but is a useful option in many developing countries. When patients with Dent disease undergo a kidney transplant, it has been found that nephrocalcinosis does not reoccur. Kidney

QUESTIONS TO ASK YOUR DOCTOR

- Because the disease is so rare, which professionals are most knowledgeable in the treatment of Dent disease?
- Should I or other family members undergo genetic testing for Dent disease?
- What are the optimal treatment options available?
- If my kidneys fail, will a kidney transplant help me?
- Where can I go for the latest information about research on Dent disease?

transplantation may therefore be an effective option for some patients.

Prognosis

The prognosis of Dent disease 1 is generally poor; in one study of patients diagnosed with Dent disease, 9 out of 15 men developed ESRD by age 47. In addition, decreased renal function is believed to be caused in part by infection and obstruction due to kidney stones.

Because Dent disease is so rare, most physicians have no experience with it. Consequently, in order to familiarize the medical community worldwide about Dent disease, an international registry was established at the Mayo Clinic in Rochester, Minnesota. The registry, called the Dent Disease Registry (or the International Registry for Calcium Stone Diseases), helps to increase understanding of the disease and eventually to establish guidelines for the diagnosis and treatment of the disease. In addition, this concerted effort is providing valuable information concerning Dent disease, which helps biomedical researchers and clinicians to increase knowledge.

Dentatorubral-pallidoluysian atrophy

Definition

Dentatorubral-pallidoluysian atrophy (DRPLA) is a disorder of ataxia (loss of balance), choreoathetosis (involuntary rapid, irregular, jerky movements or slow, writhing movements that flow into one another), and dementia (inability to clearly think; confusion, poor judgment; failure to recognize people, places, and things; personality changes) in adults, and ataxia, myoclonus (involuntary spasms of a muscle or muscle group), epilepsy (seizures), and loss of intellectual function (intellectual disability) in children.

The name of the disorder is derived from the names of several anatomical structures in the cerebellum and basal ganglia of the brain: "dentato-" refers to the dentate nucleus in the cerebellum, "rubral" to the red nucleus in the mid-brain, "pallido-" to the globus pallidus in the basal ganglia, and "luysian" to the subthalamic nucleus in the basal ganglia. The subthalamic nucleus is sometimes called the corpus Luysi or Luys' body, after the French anatomist Jules Bernard Luys, who first described it in 1865.

Description

DRPLA is also known as Haw River syndrome, Natito-Oyanagi disease, and myoclonic epilepsy with choreoathetosis. The typical age of onset of DRPLA is 30 years, but it can present in people as young as one year of age and

as old as 62 years of age, with differences in presentation between children and adults. In patients under the age of 20, DRPLA presents as seizures, ataxia, and myoclonus, as well as progressive (worsening) mental deterioration. In patients over the age of 20, DRPLA is suspected when a person develops ataxia, choreoathetosis, dementia, and psychiatric disturbances (delusions, hallucinations). A positive family history (a relative with similar symptoms or one already diagnosed) confirms the diagnosis.

DRPLA is sometimes initially thought to be Huntington's disease. A possible diagnosis of DRPLA can be devastating for a family to experience—their once healthy child, or young adult, will begin to have seizures, involuntary movements, loss of control over voluntary movement, and delusions—perhaps no longer being able to identify family members. Diagnosing DRPLA is complicated and requires a knowledgeable physician with expertise in both neurology and genetics. Usually an individual diagnosed with DRPLA already has a parent with the disease; however, if the disorder had not been diagnosed properly, the parent died prior to the onset of symptoms, or the parent has very late onset of the disease, there may not be a documented family history of DRPLA.

Genetic profile

DRPLA is an autosomal dominant condition, which means that both males and females are equally likely to have the disease, and an individual with the variant gene has a 50/50 chance to pass the condition to any child. The gene associated with DRPLA is known as the atrophin-1 gene or *ATN1*, and is located on the short arm of chromosome number 12 at 12p13.31. The gene has a section of DNA in which the DNA alphabet is repeated in triplets called CAG (cytosine-adenine-guanine) repeats. Normally a person has 6 to 35 CAG repeats in the *ATN1* gene. In patients with DRPLA, there are 49 to 88 repeats that cause the gene's protein product, atrophin 1, to be toxic to cells. Although scientists do not understand the exact mechanism, the number of repeats expands when the gene is transmitted from parent to child. The length of the repeat transmitted to the next generation depends upon the length of the parent's repeat and the sex of the transmitting parent.

There is an inverse correlation between the age of onset and the size of the expanded CAG repeats. In other words, the younger the age of onset, the larger the number of CAG repeats:

- Onset before age 21—repeat range of 63–69 (average of 68)
- Onset from 21 to 40 years—repeat range of 61–69 (average of 64)

- Onset after 40 years—repeat range of 54–63 (average of 63)

Although there is significant overlap, the inverse correlation exists.

DRPLA exhibits a phenomenon known as anticipation, which is found in other genetic conditions. Anticipation means that the disease increases in severity and presents at a younger age of onset with each successive generation. For example, when the CAG repeat is inherited from the father, DRPLA can manifest itself 28 years earlier in the offspring than the age at which the father began having symptoms. If transmitted from the mother, DRPLA can present 15 years earlier than in the previous generation.

Demographics

DRPLA has been reported to occur most often in the Japanese population, although it has been described in other ethnic groups, including those in Europe and North America. The prevalence of DRPLA in the Japanese population is estimated to be 2–7 in 1,000,000, which is similar to the prevalence of Huntington's disease in this population. A CAG repeat size of 17 or higher (usually 20–35) is more common in healthy Japanese individuals than in Caucasians, which may explain why DRPLA is more common in the Japanese. In other words, a larger repeat size in a parent increases the possibility that the DNA will become unstable and expand when transmitted to the next generation. Even though DRPLA is rare in the United States, five generations of an African-American family in North Carolina, where the condition is also called the Haw River syndrome, have suffered from DRPLA.

Signs and symptoms

The cardinal features of DRPLA are involuntary movements (usually in the face, neck, tongue, and hands) and dementia (inability to clearly think; confusion; poor judgment; failure to recognize people, places, and things; personality changes) regardless of the age of onset. A history of ataxia, epilepsy, and intellectual disability in children, combined with a positive family history, are often the presenting signs of this condition in an individual under 20 years of age. Seizures are always present in patients under 20, but they are not as common in patients aged 20–40 and rarely seen in patients with onset after 40. Adult-onset DRPLA (after age 20) presents with ataxia, choreoathetosis, dementia, and psychiatric disturbances. Other symptoms that have been reported include degeneration of the cornea of the eye and obstructive sleep apnea that does not respond to surgical treatment.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy.

Anticipation—Increasing severity in disease with earlier ages of onset in successive generations; a condition that begins at a younger age and is more severe with each generation.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Basal ganglia—A group of small compact groups of nerve cells (called nuclei) located at the base of the forebrain. The various nuclei govern such functions as control of voluntary movements, routine behaviors, cognition, and emotion.

Cerebellum—The portion of the human brain that lies underneath the cerebral hemispheres at the back of the brain overlying the brain stem. It is responsible for the control and coordination of movement.

Choreoathetosis—Involuntary rapid, irregular, jerky movements or slow, writhing movements that flow into one another.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted through either the mother’s vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Dementia—A condition of deteriorated mental ability characterized by a marked decline of intellect and often by emotional apathy.

DNA repeats—A three-letter section of DNA called a triplet, which is normally repeated several times in a row. Too many repeats often cause the gene to malfunction, resulting in disease.

DRPLA—Dentatorubral-pallidolysian atrophy; also called Haw River syndrome and Natito-Oyanagi disease. DRPLA is a disorder of ataxia, choreoathetosis, and dementia in adults, and ataxia, myoclonus, epilepsy, and intellectual disability in children.

Epilepsy—A seizure disorder.

Myoclonus—Twitching or spasms of a muscle or an interrelated group of muscles.

Sporadic—Isolated or appearing occasionally in a population with no apparent pattern.

Diagnosis

A diagnosis of DRPLA is made when there is a positive family history of the disease, characteristic clinical findings, and DNA testing that reveals an expansion in the CAG repeat of the *ATN1* gene. Genetic testing to examine the CAG repeats in the *ATN1* gene can be performed from a small blood sample. A few reports have described DRPLA as sporadic (occurring by chance) in some families. Upon closer examination, the asymptomatic fathers had a mildly expanded CAG repeat size. Therefore, it is always important to evaluate both parents of an affected individual even if they appear to have no symptoms of DRPLA. Testing of asymptomatic children is not appropriate since it takes away the child’s right to want to know or not know this information. It also raises the possibility of stigmatization (labeling someone a certain way and making assumptions about them) within a

family, as well as the threat of educational and employment discrimination. Children *with* symptoms, however, usually benefit from having a diagnosis established.

For pregnancies at 50% risk, prenatal diagnosis is available via either CVS (chorionic villus sampling) or amniocentesis. CVS is a biopsy of the placenta performed in the first trimester of pregnancy under ultrasound guidance. Ultrasound is the use of sound waves to visualize the developing pregnancy. The genetic makeup of the placenta is identical to that of the fetus (developing baby), and therefore the *ATN1* gene can be studied from this tissue. There is approximately a 1 in 100 chance for miscarriage with CVS. Amniocentesis is a procedure done under ultrasound guidance in which a long, thin needle is inserted into the mother’s abdomen, into the uterus, to withdraw a couple of tablespoons of amniotic fluid (fluid surrounding the developing baby) to study. The *ATN1*

QUESTIONS TO ASK YOUR DOCTOR

- At what stage of a person's life do the symptoms of dentatorubral-pallidoluysian atrophy first appear?
- What treatments are available for this condition, and does the plan of treatment differ for various age groups?
- If I have an older sister with dentatorubral-pallidoluysian atrophy, what are the chances that I might develop the disorder also?
- How long does a person live after a diagnosis of dentatorubral-pallidoluysian atrophy, and what are the usual causes of death for this disease?

gene can be studied using cells from the amniotic fluid. Such other genetic tests as a chromosome analysis may also be performed with either CVS or amniocentesis. A small risk of miscarriage (1 in 200 to 1 in 400) is associated with amniocentesis.

Treatment and management

There is currently no cure for DRPLA; treatment is supportive. Epilepsy is treated with antiseizure medications. Psychiatric disturbances can be treated with appropriate psychotropic medications. Children diagnosed with DRPLA may benefit from special education programs tailored to their individual needs.

Prognosis

The prognosis for DRPLA is poor, as there was no cure as of 2021. Patients with DRPLA have progressive disease, which means symptoms become worse over time. The average duration of the disease is 13 years, followed by death due to difficulty swallowing and bronchopneumonia following increasingly severe seizures. The patient's lifespan is reduced by the disease, although a few patients have been reported to live as long as 60 years.

Depression

Definition

Depression is the general name for a family of illnesses known as depressive disorders. It affects not only the mood and thoughts but also the physical functions of affected individuals. Depressive disorders usually result from a combination of genetic, environmental, and psychological factors. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, text revision (DSM-V) defines a major depressive episode (MDE) as a period of two weeks or longer during which there is either depressed mood or loss of interest or pleasure (anhedonia), and at least four other symptoms that reflect a change in functioning, such as problems with sleep, eating, energy, concentration, and self-image.

Description

Everyone feels sadness, grief, or despair at some point in their lives. However, unlike these normal, transient emotional states, a depressive disorder is not a temporary bout of "feeling down" but rather a serious illness

PET scans comparing a normal human brain (top) to the brain of a person suffering from depression. (*Science Source*)

that should be recognized and treated as a medical condition. Without treatment, a depressive disorder can persist, and its symptoms can go on for weeks, months, or years. The three most common types of depression are dysthymic disorder, major depression, and bipolar disorder.

Depression is quite widespread and one of the leading causes of disability in the world. Commonly recognized symptoms of all types of depressive disorders are recurring feelings of sadness and guilt, such changes in sleeping patterns as insomnia or oversleeping, changes in appetite, decreased mental and physical energy, unusual irritability, the inability to enjoy once-favored activities, difficulty in working, and thoughts of death or suicide. If only these “down” symptoms are experienced, the individual may suffer from a unipolar depressive disorder such as dysthymia or major depression. If the depressed periods alternate with extreme “up” periods characterized by unusual energy levels, the individual may have a bipolar disorder.

Dysthymic disorder is a relatively mild depressive disorder that is characterized by the presence of two or more of the symptoms listed above. The symptoms are not severe enough to disable the affected individual, but they are long-term (chronic) and may last for several years. Individuals affected by dysthymic disorder often experience episodes of major depression at some point in their lives.

In cases of major depression, the affected individual has five or more symptoms and experiences one or more prolonged episodes of depression that last longer than two weeks. These episodes can render the person unable to function. Individuals experiencing an episode of major depression often entertain suicidal thoughts, which make this disorder very serious. Some individuals affected by major depression may experience only a single bout of disabling depression in their lifetimes. More commonly though, affected individuals experience recurrent disabling episodes throughout their lives.

Bipolar disorder, formerly called manic depression or manic-depressive illness, is not nearly as common as major depression and dysthymia. It is associated with alternating periods of extreme excitement (mania) and periods of extreme sadness (depression). The rate of the transition between cycles is usually gradual, but the mood swings may also be severe and dramatically rapid. When in the depressive state, affected individuals may show any or all of the common symptoms of depression. In the manic state, they may feel restless and unnaturally elated, have an overabundance of confidence and energy, and be very talkative. Mania can distort social behavior and judgment, causing the affected individual to take excessive risks and perhaps make imprudent decisions that can have humiliating or damaging consequences. Without medical treatment, bipolar disorder may progress into psychosis.

One subset of depressive disorder is seasonal affective disorder (SAD), in which the person loses energy, sleeps a great deal, tends to overeat, and shows other symptoms associated with depression during a specific season (most often the winter, but there are also patients who experience SAD during the summer months) but has consistent mental health the rest of the year. SAD is also called the winter blues, summer sadness, or seasonal depression.

Depressive disorders are believed to be related to imbalances in brain chemistry, particularly in relation to the chemicals that carry signals between brain cells (neurotransmitters), as well as the hormones released by parts of the brain. Serotonin and norepinephrine are two important neurotransmitters. Disruption of the brain’s circuits in areas involved with emotions, appetite, sexual drive,

and sleep is a likely cause of the dysfunctions associated with depressive disorders. Thus, some treatments for depression are drugs that are known to have an effect on brain chemistry.

Genetic profile

Depression is known to be genetically linked, because it often runs in families and has been studied in identical twins, but only a few specific risk genes for depression have been identified. In 2003, a group of researchers in Salt Lake City identified a gene known as *MDD1* (for major depressive disorder type 1) on the long arm of chromosome 12 at 12q22-q23.2, but little is known about this gene. In 2004, a second gene, known as *MDD2* (for major depressive disorder type 2), was identified on the long arm of chromosome 15 at 15q25.3-q26.2, but as with *MDD1*, little is known about this gene, and there are no molecular genetic tests for it.

Other genes that have been linked to susceptibility to depression include the *TPH2* gene on the long arm of chromosome 12 at 12q21.1, which codes for a protein primarily active in the brainstem and may be linked to bipolar disorder as well as major depressive disorder, and the *FKBP5* gene on the short arm of chromosome 6 at 6p21.31, which codes for a protein involved in regulating the immune system. Molecular genetic testing is available for both of these genes. A third gene, *HTR2A*, is located on the long arm of chromosome 13 at 13q14.2. *HTR2A* encodes one of the receptors for the neurotransmitter serotonin, and mutations in this gene have been linked to susceptibility to seasonal affective disorder as well as susceptibility to major depression. Molecular genetic testing is also available for this gene.

There is some evidence for convergence of linkage findings across studies, but more data are needed. Research directions include more intensive, systematic studies of linkage candidate regions and of the whole genome for accurate genetic association. According to the National Institute of Mental Health (NIMH), genetic studies of depression are now focusing on the common biological pathways (processes) that are shared by such different disorders as depression, bipolar disorder, and schizophrenia—particularly disorders that have a common age of onset. These pathways include communication between neurons and changes in the immune system. Researchers think that a better understanding of the common biological pathways affected by risk genes for various mental illnesses may yield more effective treatments than focusing on identifying and characterizing the risk genes themselves.

Genome-wide association studies (GWASs) have identified more than 80 loci associated with depression,

eight of which are unique to depression, do not overlap with other mental health disorders, and have been independently replicated. As with other complex, polygenic medical and psychiatric disorders that are phenotypically heterogeneous (they present differently), the challenge is to identify the genetic variants that are causally related to major depressive disorder. The challenge is further compounded by the observations that depression has many different causes and that many people who suffer from depression also have co-occurring mental conditions. Pleiotropy, when a genetic variant influences two or more phenotypes, also makes it harder to pinpoint specific genetic variants. GWASs have found considerable genetic overlap between depression and other mental disorders.

There are also many non-genetic factors that cause depression, including stressful environmental conditions and life events, certain illnesses, maladaptive coping patterns, and such precipitating conditions as persistent unemployment, exposure to major disasters or other traumatic events, and the loss of a close relationship. Alcohol abuse and the use of sedatives, barbiturates, narcotics, or other drugs can cause depression due to the effects of these substances on brain chemistry.

Demographics

Worldwide, depression affects more than 300 million people, and it is the most common cause of disability in people under age 60. According to the most recent (2019) statistics available from the Centers for Disease Control and Prevention (CDC), nearly 5% of the American population over the age of 18 report current depression. In every age group, women report higher rates of depression than men. Although the average age at onset of a major depressive episode is 32, the highest rates of depression for both sexes are in the 40–59 age bracket (12% for women and 7% for men), with both older and younger adults reporting somewhat lower rates. On average, eight million Americans per year receive a primary diagnosis of major depressive disorder when they seek treatment from primary care physicians, hospital emergency departments, and outpatient mental health clinics.

The National Institute of Mental Health (NIMH) confirms that many people suffer from more than one mental disorder at a given time. Nearly half (45%) of those with any mental disorder meet criteria for two or more disorders.

That women experience depression at a rate that is almost twice that of men may be partially explained by the greater willingness of women to seek psychological treatment, but this factor does not explain the entire discrepancy. Many physical events specific to women, such

as menstruation, pregnancy, miscarriage, the postpartum period, and menopause, are recognized as factors contributing to depression in women. Women in the United States may face environmental stressors with a higher frequency than men. For example, most single-parent households are headed by women; women still provide the majority of child and elder care, even in two-income families; and women are generally paid less than men, so their financial concerns may be greater.

Particular demographic problems associated with the disorder include depression in the elderly, children, and adolescents. One common belief is that depression is normal in older adults. This is not so, although increasing age, the side effects of medications taken by older adults for treatment of physical problems, and the loss of interpersonal relationships are associated with depression. Because of this misconception, depressive disorders in older adults are often overlooked, undiagnosed, and untreated. Similarly, many parents often ignore the symptoms of a depressive disorder in their children, assuming that these symptoms are merely a developmental phase that the child will outgrow.

Signs and symptoms

Individuals affected with depressive disorders display a wide range of symptoms, which vary in severity from person to person and over time in a single affected individual.

Symptoms that characterize a depressive state include feelings of hopelessness, guilt, or worthlessness; a persistent sad or anxious mood; restlessness or irritability (more common in men); anhedonia (loss of interest in activities that were once considered pleasurable); difficulty concentrating, remembering, or making decisions; sleep disorders, including insomnia, early morning awakening, and/or oversleeping; constant fatigue; eating disorders, including weight loss, loss of appetite, or overeating; suicidal thoughts and/or tendencies; and persistent physical symptoms that do not respond to normal treatments of these symptoms, such as headaches, digestive problems, and chronic pain.

Symptoms that characterize a manic state include increased energy accompanied by a decreased need for sleep, a loss of inhibitions accompanied by inappropriate social behavior, excessive enthusiasm and verve, increased talking, poor judgment, a feeling of invincibility, grandiose thinking and ideas, unusual irritability, and increased sexual desire.

Symptoms that characterize seasonal affective disorder include difficulty waking in the morning; overeating, particularly heavy, carbohydrate-rich foods; weight gain; difficulty concentrating on or completing tasks; social

withdrawal; irritability; and decreased sex drive. In contrast to MDD, however, the symptoms of SAD are limited to a particular season of the year and usually remit during the rest of the year.

Diagnosis

Depression is notoriously difficult to diagnose, because its symptoms are not readily apparent to the medical professional unless the patient first recognizes and admits to them. Once the individual seeks help for his or her symptoms, the first step in the diagnosis of a depressive disorder is a complete physical examination to rule out any medical conditions, viral infections, or medications that may produce the effects also seen in depression. Laboratory tests that may be ordered include a complete blood count (CBC), liver function tests, blood urea nitrogen (BUN) and creatinine test, HIV test, tests to measure electrolyte levels, tests to measure thyroid hormone levels, and the rapid plasma reagin (RPR) test for syphilis.

Alcohol or other drug abuse as a possible cause of the observed symptoms should also be investigated; this investigation is usually accomplished with a blood and urine toxicology screen and a blood alcohol test. If the doctor suspects that an organic brain disorder may be the cause of the patient's symptoms, a CT scan or MRI may be ordered; however, imaging studies cannot be used in isolation to diagnose depression.

Once a physical basis for these symptoms is eliminated, a complete psychological exam should be undertaken. This examination consists of a mental status examination, a complete history of current and previously experienced symptoms, and a family history.

The mental status examination is used to determine the presence of a more severe psychotic condition. This mental status examination will also determine whether the depressive disorder has caused changes in speech or thought patterns or memory that may indicate the presence of a depressive disorder. The complete psychological exam also includes a comprehensive history of the symptoms experienced by the affected individual. This history includes the onset of the symptoms, their duration, and whether or not the affected individual has had similar symptoms in the past. In the case of past symptoms, a treatment history should be completed to assess whether these symptoms previously responded to treatment, and if so, which treatments were effective. The final component of the complete psychological exam is the family history. In cases in which the symptomatic individual has had similarly affected family members, a treatment history should also be completed (to the extent possible) for these family members.

Most patients suffering from depression are seen first by a primary care physician rather than a psychiatrist. There are questionnaires and self-report instruments that physicians who are not specialists in psychiatry can use to evaluate a patient who appears to have the symptoms of a mood disorder. These include the Beck Depression Inventory, the Zung Self-Rating Depression Scale, the Geriatric Depression Scale (which has also been found useful in younger adults), and the Patient Health Questionnaire (PHQ) nine-item scale for depression. The simplest screener is a two-question test: (1) During the past month, has the patient been troubled by feeling “down,” depressed, or hopeless? (2) During the past month, has the patient been troubled by losing interest or pleasure in his or her usual activities? Although these screeners and self-report inventories are not a substitute for a formal psychiatric evaluation, they can guide the patient’s primary care physician in making a needed referral to a psychiatrist.

The diagnostic criteria for a major depressive episode (MDE), according to DSM-5, are as follows:

A. Five or more of the following symptoms must be experienced for at least two weeks and must represent a change in functioning. At least one symptom is either depressed mood or loss of interest or pleasure. The doctor is instructed to exclude symptoms that are clearly related to a general medical condition, as well as delusions or hallucinations.

- Depressed mood nearly every day, as reported either by the patient or by others. In children and adolescents, this symptom may be primarily irritability.
- Marked loss of interest or pleasure in activities most of the day or nearly every day, as reported either by the patient or by others.
- Significant weight loss when not dieting, or a weight gain of more than 5% of body weight, or a noticeable decrease or increase in appetite nearly every day.
- Insomnia or hypersomnia (oversleeping) nearly every day.
- Agitation or psychomotor retardation nearly every day that is observable by others.
- Fatigue or significant loss of energy nearly every day.
- Feelings of worthlessness or guilt most days (not feelings of self-reproach or guilt for being sick). These feelings may be delusional.
- Indecisiveness or inability to concentrate on tasks, as reported either by the patient or by others, nearly every day.
- Recurrent thoughts of death (not simply fear of dying); thoughts of suicide, with or without a plan for

committing suicide; a specific plan for committing suicide; or an actual suicide attempt.

B. The symptoms cause considerable distress and impairments in social, educational, or occupational functioning.

C. The symptoms are not due to the direct effects of a substance (prescription medication, alcohol, or drug of abuse) or a general medical condition.

Treatment and management

Treatment of depression is done on a case-by-case basis and largely depends on the outcome of the psychological examination. Some mildly affected individuals respond fully to psychotherapy and do not require medication. Others with moderate or severe depression benefit from antidepressant medications. Most affected individuals respond best to a combination of antidepressant medication and psychotherapy: the medication to provide relatively rapid relief from symptoms of depression, and psychotherapy to learn effective ways to manage and cope with problems and issues that may cause the continuation of symptoms or the onset of new symptoms of depression.

Various types of antidepressant medications are available for the treatment of depressive disorders. Many individuals affected by depression will go through a variety of antidepressants, or antidepressant combinations, in a kind of trial-and-error comparison, before the best medication and dosage for them is identified. Almost all antidepressant medications must be taken regularly for at least two months before the full therapeutic effects are realized. A full course of medication is generally no shorter than six to nine months to prevent recurrence of the symptoms. In individuals affected with bipolar disorder or chronic major depression, medication may have to be continued throughout the remainder of their lives. These time-related conditions often pose problems in the management of individuals affected with depressive disorder. Many individuals who have a depressive disorder discontinue their medications before the fully prescribed course for a variety of reasons. Some experience side effects of the medications prior to feeling any benefits, and others think that the medication is not helping because of the delay between the initiation of the treatment and the feelings of symptom relief, and they many feel better prior to the full course and so cease taking the medication.

Three commonly prescribed antidepressant drug classes consist of the older tricyclics (TCAs) and two other drug classes: the selective serotonin reuptake inhibitors (SSRIs) and the monoamine oxidase inhibitors (MAOIs). The most common TCAs are amitriptyline (Elavil), clomipramine (Anafranil), desipramine (Norpramin, Pertofrane), doxepin (Sinequan, Adapin), imipramine (Tofranil, Janimine),

nortriptyline (Pamelor, Aventyl), protriptyline (Vivactil), and trimipramine (Surmontil). The most common SSRIs are citalopram (Celexa), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft). The most common MAOIs are phenelzine (Nardil) and tranylcypromine (Parnate).

A fourth and newer class of antidepressant medication are the serotonin-norepinephrine reuptake inhibitors, or SNRIs. These drugs work by preventing the reuptake of norepinephrine as well as serotonin and appear to be more effective than the SSRIs, as well as having better safety profiles. The SNRIs include such drugs as venlafaxine (Effexor), duloxetine (Cymbalta), and desvenlafaxine (Pris-tiq). The SSRIs and the SNRIs have largely displaced the older tricyclics and MAOIs.

Many antidepressant medications cause such side effects as agitation, bladder problems, blurred vision, constipation, drowsiness, dry mouth, headache, insomnia, nausea, nervousness, or sexual problems. Most of these side effects subside as the treatment course progresses. The tricyclics cause more severe side effects than the newer SNRIs, SSRIs, or MAOIs.

In the most severely affected individuals, or those for whom antidepressant medications either have not worked or cannot be taken, electroconvulsive therapy (ECT) may be considered. In the ECT procedure, electrodes are put on specific locations on the head to deliver electrical stimulation to the brain. This electrical stimulation is designed to trigger a brief seizure within the brain. These seizures generally last approximately 30 seconds and are not consciously felt by the patient. ECT has been much improved in recent years; it is no longer the electroshock treatment of nightmares, and its deleterious effects on long-term memory have been reduced. ECT treatments are generally administered several times a week as necessary to control the symptoms being experienced.

Several short-term (10- to 20-week) psychotherapies have also been demonstrated to be effective in the treatment of depressive disorders. These include interpersonal and cognitive/behavioral therapies. Interpersonal therapies focus on the interpersonal relationships of the affected individual that may both cause and heighten the depression. Cognitive/behavioral therapies focus on ways in which affected individuals may be able to change their patterns of thinking or behaving that may contribute to episodes of depression. Psychodynamic therapies, which generally are not short-term psychotherapies, seek to treat the individual with a depressive disorder through resolution of internal conflicts. Psychodynamic therapies are generally not initiated until major depressive episodes have ceased or until the symptoms of depression are significantly improved by medication or one of the short-term psychotherapies.

KEY TERMS

Anhedonia—The inability to experience satisfaction or pleasure from activities or interests that the person previously enjoyed. It is a common symptom of depression.

Bipolar disorder—Formerly called manic depression, this psychological disorder is characterized by periods of mania followed by periods of depression.

Cognitive/behavioral therapies—Psychological counseling that focuses on changing the thinking and behavior of the patient.

Dysthymia—A psychological condition of chronic depression that is not disabling but prevents the sufferer from functioning at his or her full capacity.

Electroconvulsive therapy—A treatment in which a series of controlled electrical impulses are delivered to the brain in order to induce a seizure.

Grief reaction—The normal sadness felt after a traumatic major life occurrence, such as the loss of a loved one.

Interpersonal therapies—This type of psychological counseling focuses on determining how dysfunctional interpersonal relationships of the affected individual may be causing or influencing symptoms of depression.

Major depression—A psychological condition in which the patient experiences one or more disabling bouts of depression lasting two or more weeks.

Polygenic—Referring to a trait, characteristic, or condition, that depends on the activity of more than one gene for its emergence or expression.

Psychodynamic therapies—A form of psychological counseling that seeks to determine and resolve the internal conflicts that may be causing an individual to be suffering from symptoms of depression.

Psychotherapy—Psychological counseling that seeks to determine the underlying causes of a patient's depression. The form of this counseling may be cognitive/behavioral, interpersonal, or psychodynamic.

Seasonal affective disorder (SAD)—A subset of depressive disorder in which the person experiences depressive symptoms in the winter (or summer) but feels normal the rest of the year. SAD is also called the winter blues, summertime sadness, or seasonal depression.

QUESTIONS TO ASK YOUR DOCTOR

- Which medications are available for treating my family member's depression?
- Are there treatments and procedures other than medication that may be helpful in treating his or her condition?
- Are there side effects for the medications used in the treatment of depression?
- Are there changes that we can make in our loved one's lifestyle that will reduce his or her risk of depression?

Clinical trials

Clinical trials on the treatment of depression are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2021, there were more than 865 clinical trials underway for various interventions for depression in the United States alone. Some of these trials involve investigational drugs, psychological interventions using e-health and social media; the use of intermittent theta burst transcranial magnetic stimulation (iTBS); interventions that target specific subpopulations (older adults, adolescents, Hispanics, low-income patients, women in perimenopause, military personnel, women who have just given birth, people with diabetes, and cancer patients); and alternative/integrative therapies like mindfulness meditation, yoga, tai chi, and relaxation techniques.

Prognosis

More than 80% of individuals affected with a depressive disorder have demonstrated improvement after receiving the appropriate combination of treatments. However, each depressive episode increases the patient's risk of a recurrence of MDD. About half of all patients who recover from MDD will have another episode over the course of their life, and around 15% of those will develop chronic depression. The risk of recurrence is higher in patients whose symptoms did not fully resolve with treatment.

One significant tragedy associated with depression is the failure of many affected individuals to realize that they have a treatable medical condition. There have been calls for depression screening from medical professional societies, and in 2016 the U.S. Preventive Services Task Force (USPSTF) concluded, "There is a moderate net benefit to screening for depression in adults, including older adults, who receive care in clinical practices that have adequate systems in place to ensure accurate diagnosis, effective

treatment, and appropriate follow-up after screening. The USPSTF also concludes with at least moderate certainty that there is a moderate net benefit to screening for depression in pregnant and postpartum women who receive care in clinical practices that have CBT or other evidence-based counseling available after screening." Absent widespread screening for depression, only about half of patients with major depression will be identified. Some affected individuals who do not receive treatment may recover completely by themselves, but most will suffer needlessly. A small number of individuals with depressive disorder do not respond to current methods of treatment.

Diabetes

Definition

“Diabetes” is the Greek term for “passing through,” a phrase used to describe multiple distinct disorders characterized by excessive urination. Diabetes mellitus, the most common form of diabetes, is a chronic disorder of carbohydrate metabolism, characterized by the inadequate secretion or utilization of the hormone insulin and an excessive amount of sugar (glucose) in the blood and urine. Diabetes is a major cause of death in the United States and other developed countries. A multitude of different genes and gene variants (alleles) have been associated with different types of diabetes. However, the interactions of these various genes with one another and with environmental and lifestyle factors are poorly understood. Furthermore, various genes have profound effects on risk factors for diabetes, such as obesity, and on the development of various pathologies associated with diabetes. Finally, regulatory DNA sequences that turn genes

on and off, as well as modifications to individual nucleotides in DNA (known as epigenetic effects), appear to be important for the development of diabetes.

Description

The four major types of diabetes are:

- type 1 diabetes mellitus (T1D), also called insulin-dependent diabetes mellitus (IDDM)
- type 2 diabetes mellitus (T2D), also called non-insulin-dependent diabetes mellitus (NIDDM)
- gestational diabetes mellitus (GDM)
- diabetes secondary to other conditions

Diabetes mellitus

Diabetes mellitus is characterized by excessive levels of the sugar glucose in the blood, which is consequently passed through the urine. The word “mellitus” is Latin for honey. Blood glucose comes from food, the liver, and muscle cells and is used for energy by cells throughout the body. However, chronic excessive amounts of glucose in the blood cause a variety of serious health complications.

People with diabetes mellitus have excessive blood glucose because of a deficiency in the production or utilization of the hormone insulin. Insulin is made by the beta cells of the pancreas in response to elevated glucose in the blood following a meal. It binds to receptors on the body’s cells to enable the passage into the cells of glucose for energy. Insulin stimulates cells to remove glucose from the blood and stimulates the liver to metabolize glucose so that blood glucose levels remain stable. A deficiency of insulin or defective insulin utilization (called insulin resistance or insensitivity) starves cells of glucose while resulting in high blood sugar (hyperglycemia). Chronic diabetes mellitus can lead to heart disease and serious problems with the eyes, kidneys, nervous system, gums, and teeth. People with diabetes are more than twice as likely to develop heart disease or suffer strokes.

T1D was formerly called juvenile diabetes because it is usually first identified in children or young adults. It is an autoimmune disorder in which the body’s immune system attacks and destroys the beta cells of the pancreas, preventing the production and release of insulin.

T2D is the most common type of diabetes. It was formerly called adult-onset diabetes, because it usually developed in people over age 40. However, T2D is increasingly being diagnosed in children and young adults. With T2D, the body’s cells become insulin resistant and do not properly utilize the insulin being synthesized and secreted by the pancreas. In early stages, the pancreas increases insulin production in response to the increased demand. However, as the disease progresses,

the pancreas loses the ability to secrete sufficient insulin in response to meals.

GDM is a form of glucose intolerance that may develop during the late stages of pregnancy due to pregnancy hormones or insulin deficiency. It requires treatment to normalize maternal blood glucose levels and avoid complications in the infant. It usually disappears after childbirth, but women with GDM have a 20%–50% chance of developing T2D within 5–10 years. Pre-existing diabetes that is not successfully controlled before conception and during the first trimester of pregnancy may result in major birth defects in 5%–10% of pregnancies and spontaneous abortions in 15%–20% of pregnancies. If diabetes is uncontrolled during the second and third trimesters of pregnancy, dangerously high infant birth weights can result.

Prediabetes is a condition in which blood glucose levels are abnormally elevated and that may progress to T2D. It involves impaired fasting glucose (IFG), impaired glucose tolerance (IGT), or both. With IFG, the blood sugar level is elevated to between 100 and 125 milligrams per deciliter of blood (mg/dL) after an overnight fast. With IGT, the blood sugar level is

elevated to between 140 and 199 mg/dL after a two-hour oral glucose tolerance test. The risk of prediabetes progressing to T2D can be significantly reduced by moderate weight loss and physical activity.

The risk of death among individuals with diabetes is approximately twice that of people without the disorder. Adults with diabetes have two to four times the increased risk for both cardiac disease and stroke. Cardiac disease and stroke are leading causes of diabetes-related mortality, responsible for 65% of deaths in people with diabetes. Approximately 73% of adults with diabetes have elevated blood pressure or use prescription medications for hypertension. Diabetic retinopathy is the leading cause of new cases of adult blindness. Approximately 60%–70% of people with diabetes have some degree of nervous system damage (neuropathy). Severe forms of diabetic neuropathy account for more than 60% of non-traumatic lower-limb amputations in the United States.

Other types of diabetes

Diabetes insipidus is caused by insufficient vasopressin (antidiuretic hormone or ADH) produced by the pituitary gland or by failure of the kidneys to respond to

Type 2 diabetes: pedigree analysis chart (Gale)

vasopressin. This causes an abnormal amount of water to be secreted in the urine, resulting in excessive urination, thirst, weakness, and dry skin. Diabetes insipidus is often inherited, especially when it occurs in children.

Myotonic dystrophy, Friedreich's ataxia, and Wolfram's syndrome (an autosomal recessive neurodegenerative disorder that includes diabetes insipidus, diabetes mellitus, and deafness, among other problems) are a few of the other hereditary disorders that involve diabetes.

Genetic profile

Type 1 and type 2 diabetes mellitus are complex polygenic disorders, and although they have different causes, they may have genetic components in common. A combination of an inherited predisposition to diabetes and environmental factors appears to contribute to the development of both types, but genetic predisposition does not necessarily result in the development of diabetes.

T1D

Susceptibility or predisposition to T1D runs in families, and heritability is higher for individuals who have first-degree relatives with the disease. Identical twin studies have revealed that if one twin has T1D, the other twin has at most only a 50% chance of the disorder. It is believed that in most cases of T1D, risk factors are inherited from both parents. In general, a child of a man with T1D has a 1 in 17 chance of developing the disorder. A child born to a woman under age 25 with T1D has a 1 in 25 chance of developing the disorder, but the risk is only 1 in 100 if the mother was 25 or older when she gave birth. If both parents have T1D, their child's risk is 10%–25%. If a parent developed T1D before age 11, the child's risk of T1D is doubled. About 1 in 7 people with T1D also have a thyroid and adrenal gland condition called type 2

polyglandular autoimmune syndrome. Their children are at 50% risk of developing both disorders. As of 2021, hundreds of gene loci had been associated with risk for T1D. Among these are *IDDM 1* on chromosome 6, *IDDM 2* on chromosome 11, and *PTPN 22* with a mutation at LYP (lymphocyte-specific phosphatase gene) on chromosome 1.

T1D is considered to be an autoimmune disease in which immune-system cells damage insulin-producing beta cells. Certain variants of the genes *HLA-DQA1*, *HLA-DQB1*, and *HLA-DRB1* increase the risk of T1D. These genes belong to a gene family called the human leukocyte antigen (HLA) complex and produce proteins that help the immune system distinguish between the body's own proteins and foreign proteins such as those from bacteria and viruses. Researchers have, however, focused on the HLA (human leukocyte antigen) complex on chromosome 6p21, because it contributes about 50% of the genetic risk for T1D. There are many different alleles or variations in these genes, and certain combinations of these alleles are associated with an increased risk for an autoimmune response to beta cells and the development of T1D. These combinations account for about 40% of the genetic risk for T1D. Nevertheless, only about 5% of people with these combinations develop T1D. Other HLA alleles, called protective haplotypes, appear to help protect against T1D.

The *INS* gene, located on chromosome 11, produces insulin. Certain alleles in the *INS* gene may contribute to susceptibility to T1D and T2D. The associated T1D risk has been localized to a region flanking the *INS* gene that contains a short sequence of DNA that is tandemly repeated many times. The number of repeats varies among individuals, called variable number tandem repeats (VNTRs). There are three classes of VNTRs in the insulin gene. Class I includes alleles with 26–63

repeat units, class II includes alleles with approximately 80 repeats, and class III has alleles with 141–209 repeats.

Class I alleles account for 70% of the VNTR alleles. Almost all other alleles are class III. Class I VNTRs are most common in Caucasians, who have the highest rate of T1D. Class III alleles are protective against diabetes. The presence of at least one class III allele is associated with a threefold reduction in the risk of T1D. Class III VNTR alleles are associated with higher levels of insulin in the thymus. The thymus gland has an important role in training the immune system to not attack the body's own cells. Immature immune cells called T cells are presented with chains of amino acids, such as insulin, to recognize as "self." Any T cells that respond to or bind to these chains are deleted to prevent autoimmunity. Because the longer VNTRs result in more insulin in the thymus, the detection and deletion of these autoreactive T cells may be more efficient, improving immune tolerance to insulin and reducing the risk of T1D.

Most people who carry risk genes for T1D do not develop the disorder. Therefore, it is likely that environmental triggers are also involved. These triggers may include the following:

- cold weather, since T1D is more common in cold climates and develops more frequently during winter months
- diet in early life, since T1D is less common in children who were breastfed and started eating solid food at a later age
- viruses

T2D

T2D is more strongly linked to genetic inheritance than T1D. T2D tends to run in families because families tend to share environmental factors such as diet and exercise. Furthermore, obesity is a major risk factor for T2D and is, at least in part, inherited. T2D can also cause obesity. If one identical twin has T2D, the other twin has a 75% chance of also developing T2D. In general, children have a 1 in 7 chance of developing T2D if a parent was diagnosed with T2D before age 50, and a 1 in 13 chance if the parent was diagnosed after age 50. If both parents have T2D—or if one parent has a rare type called maturity-onset diabetes of the young (MODY)—a child's risk of T2D is about 1 in 2.

More than 150 DNA variations have been identified as associated with T2D, but in most cases their contribution to the disorder is unknown. It is believed that each of these many gene variants may make a small contribution to the risk of developing T2D by interacting with various environmental factors. T2D-associated genes include *ABCC8*, which is involved in insulin secretion and production of glucose; *GLUT2*, which aids in transporting glucose into the pancreas; and *GCGR*, which is involved in regulating glucose. Other genes associated with T2D include *KCNJ11*, *TCF7L2*, *PPARG*, *FTO*, *NOTCH2*, *WFS1*, *IGF2BP2*, *SLC30A8*, *JAZF1*, and *HHEX*. *KCNJ11* encodes a potassium channel on the surface of beta cells, and variations in the *KCNJ11* gene

Type 1 diabetes: pedigree analysis chart (Gale)

Genetic therapy for diabetes. Stem cells can be harvested from human embryonic material (upper left) or from bone marrow (lower left). Researchers engineer islet cells by adding genes that stimulate cell proliferation, but because such cell lines no longer produce insulin, the cell lines are further engineered to express the beta islet cell gene, *PDX-1*, which stimulates the expression of the insulin gene. The genetically engineered beta cells are infused into the liver where they begin to produce insulin. (Carol And Mike Werner/Science Source)

have been associated with both decreased and increased insulin release. *TCF7L2* regulates the production of glucagon-like peptide-1. T2D-associated genes may have only subtle variations called single nucleotide polymorphisms (SNPs) that are extremely common in populations, and it is very difficult to link these common gene variations with an increased risk of developing diabetes. Many of the links that have been found seem to be important in only certain ethnic or geographical populations:

- The *CAPN10* gene produces calpain-10, a calcium-activated enzyme that breaks down proteins. SNPs in part of the *CAPN10* gene are associated with a threefold increased risk of T2D in Mexican Americans. It is thought that these genetic variants of *CAPN10* may alter pancreatic beta cell survival, insulin production, insulin action, and liver glucose production. In European, Japanese, and Samoan populations, *CAPN10* does not appear to play an important role.
- Lipoprotein lipase (LPL) is an enzyme that breaks down triglycerides. It is functionally impaired or present at low

levels in many people with T2D, and evidence suggests that insulin may help regulate LPL synthesis. One common complication of T2D is protein excreted in the urine because of chronic inflammation and kidney damage. There is a correlation between the severity of this complication and genetic variation in the *LPL* gene. SNPs in the *LPL* gene are associated with insulin resistance in Mexican Americans. The same variation is associated with coronary artery disease and may provide some of the linkage between diabetes and atherosclerosis.

- PPARgamma (peroxisome proliferator activated receptor gamma) is a transcription factor that regulates fat cell development. Variations in the *PPARG* gene influence the risk of developing obesity and T2D. The Pima Indians of Arizona, a population with a high incidence of T2D, have several SNPs in the *PPARG* gene. Other SNPs in the gene confer a degree of protection against insulin resistance and obesity.
- A nonsense mutation in the *TBC1D4* gene is associated with T2D in Greenland.

Light micrograph of insulin crystals. Endogenous human insulin is a polypeptide hormone produced by the β -cells of pancreatic islets. Insulin controls the cellular uptake, use, and storage of glucose, fatty acids, and amino acids, and inhibits the breakdown of proteins, glycogen, and fats. Insulin also plays important roles in somatic growth, cell proliferation, and adiposity. The secretion of insulin to increase the blood sugar level (and of glucagon to decrease it) is the primary mechanism of glucose homeostasis. The disease diabetes mellitus occurs when regulation of glucose levels is lost due to the destruction of β -cells (type 1 diabetes) or when body tissues develop an inability to react to insulin (type 2 diabetes). To treat type 1 diabetes, several forms of insulin are synthesized using recombinant DNA technology. (Antonio Romero/Science Source)

- In 2015, researchers reported strong associations between the risk of T2D in African-American and Hispanic-American women and variations in magnesium-related ion channel genes. T2D risk varied with the amount of magnesium intake.
- Some genetic factors also affect and predict responses to diabetes treatment. For example, diabetes caused by mutations in the *HNF1A* gene responds strongly to sulfonylurea drugs.

Nevertheless, diet, weight, and other as yet unconfirmed environmental factors are very important for the development of T2D. The majority of individuals with T2D are overweight or obese. As people migrate from regions of the world where the incidence of T2D is low to regions where the incidence is high, they develop the T2D epidemiological pattern of their adopted countries. Furthermore, T2D is increasing throughout Asia with increases in wealth and the adoption of Western-style diets.

Monogenic diabetes

Cases of monogenetic diabetes are rare cases that develop because of a mutation in a single gene. Monogenic diabetes includes MODY, which accounts for 1%–5% of diabetes in young people, as well as Donohue syndrome and Rabson-Mendenhall syndrome among others. MODY is inherited in an autosomal dominant pattern, meaning that only one mutant gene, inherited from one parent, is required to develop diabetes, even when the other copy of the gene inherited from the other parent is normal. Mutations in the *INS* gene that result in abnormal insulin cause rare forms of diabetes, including a type similar to MODY caused by an abnormal insulin, called Chicago insulin, which also is inherited in an autosomal dominant pattern. A mutation in the gene encoding islet amyloid polypeptide causes an earlier-onset and more severe type of diabetes. Mutations in the *INSR* gene that encodes the insulin receptor can also cause rare types of diabetes and may be involved in susceptibility to T2D.

The *HNF4A* gene encodes a transcription factor that is found in the liver and pancreas and is associated with T2D. *HNF4A* mutations cause a rare form of autosomal dominant diabetes. SNPs in *HNF4A* have an impact on beta cell function, increasing or decreasing insulin secretion. In the British population, individuals with SNPs that cause increased insulin secretion have a reduced risk for diabetes. In Ashkenazi Jewish and Finnish populations, four SNPs near the *HNF4A* gene have been identified as associated with T2D via an unknown mechanism that may cause pancreatic beta cell malfunction.

Rarely, mutations in mitochondrial DNA cause monogenic forms of diabetes, including various forms of MODY and maternally inherited diabetes and deafness (MIDD). Mitochondrial genes are always inherited from mothers. MIDD appears to be caused by a defect in insulin secretion.

Demographics

The incidence of diabetes has been increasing at a significant rate in most parts of the world. As of 2018, an estimated 34.2 million people in the United States—10.5% of the population—had diabetes. Of these, 7.3 million—21.4%—were undiagnosed. More than one quarter (26.8%) of U.S. adults age 65 and older had diabetes. There were 88 million Americans over age 18 who had prediabetes in 2018. T2D accounts for 90%–95% of all diabetes cases.

T1D affects nearly 1.6 million American children and adults, according to the Centers for Disease Control and Prevention (CDC). Although Caucasians are at highest risk for T1D, they have a lower incidence of T2D than other ethnic groups. Native Americans and Alaskan natives have the highest diagnosed diabetes rates in the United States, at almost 15% of their populations. Diabetes affects nearly 12% of non-Hispanic blacks, 12.5% of Hispanics, 9.2% of Asian Americans, and only 7.5% of non-Hispanic whites.

Signs and symptoms

Both T1D and T2D often develop over many years without symptoms. The symptoms of T1D, however, usually come on suddenly with extreme hyperglycemia, characterized by increased thirst, especially for sweet beverages; increased urination; weight loss despite increased appetite; nausea or vomiting; abdominal pain; fatigue; and absence of menstruation in females. T2D symptoms are similar and may also include blurred vision, frequent or slow-healing infections (including urinary tract, vaginal, and skin infections), dry and itchy skin, tingling or numbness in the hands or feet, and erectile dysfunction in men.

Diabetes affects multiple organ systems and can result in many complications. Diabetic ketoacidosis (DKA) is a complication of diabetes caused by the buildup of byproducts of fat metabolism called ketones. Ketone buildup occurs when glucose is not available as a fuel source. Ketones accumulate in the blood and are present in the urine. DKA develops when ketone levels are high enough to cause the blood to acidify. In response, the liver begins releasing glucose to use as an energy source instead of fatty acids. Because the cells cannot take in this glucose in the absence of insulin, blood glucose levels are further elevated. DKA may be the first symptom of T1D or a sign that insulin doses must be increased. In T1D, DKA also can result from infection, trauma, heart attack, or surgery. DKA is less common with T2D and usually develops incidentally under conditions of severe stress. Recurrent episodes of DKA with T2D are usually the result of poor compliance with treatment or diet. The symptoms of DKA may include the following:

- fruity breath odor
- fatigue
- appetite loss, nausea, or vomiting
- rapid deep breathing
- difficulty breathing, especially when lying down
- decreased consciousness
- mental stupor that may progress to coma
- muscular stiffness or aching
- headache
- low blood pressure

Periods of hypoglycemia or low blood sugar can occur when the balance among insulin, food intake, and physical exertion is disturbed. Symptoms of mild hypoglycemia include hunger, sweating, anxiety, and increased heart rate. Severe hypoglycemia can lead to a confused mental state, slurred speech, weakness, lack of coordination, dizziness, drowsiness, and loss of consciousness. The loss of consciousness due to low levels of blood sugar is called a hypoglycemic coma.

People with diabetes are prone to infections from even simple lacerations because of decreased immune responses. Damage to the peripheral nervous system, called diabetic peripheral neuropathy, may result in decreased blood flow and loss of sensation in the limbs. A loss of sensation in the feet can cause an infection to go unnoticed. Lack of peripheral sensation, deficient oxygen supply from decreased blood flow, and reduced immune defense put patients at risk for peripheral gangrene. Small infected cuts can progress rapidly to tissue death that may require amputation of the affected limb. Poorly controlled blood sugar also predisposes people

KEY TERMS

Allele—Any of the alternative versions of a gene that are present in the population.

Autoimmune disorder—Conditions, such as type 2 diabetes, that are caused by inappropriate immune-system activity.

Autosomal dominant—Inheritance on chromosomes other than the sex chromosomes that requires only one copy of a gene for expression of the trait.

Beta cells—The insulin-producing cells of the pancreas.

Body mass index (BMI)—A measurement based on weight and height used to categorize people as underweight, normal, overweight, or obese.

Diabetes insipidus—A disorder caused by insufficient secretion of vasopressin (antidiuretic hormone or ADH) or failure of the kidneys to respond to vasopressin, with symptoms similar to those of diabetes mellitus; it may be inherited, especially in children.

Diabetic ketoacidosis (DKA)—A life-threatening complication of diabetes mellitus.

Fasting blood glucose test (FGT)—A diabetes test that measures blood glucose after an eight-hour fast.

Gangrene—Death of tissue due to deficient or absent blood supply.

Gestational diabetes mellitus (GDM)—Diabetes that develops during pregnancy and increases the risk of type 2 diabetes.

Hemoglobin—The iron-containing pigment of red blood cells that carries oxygen.

Hemoglobin A1c (HbA1c)—A blood test that indicates average blood glucose levels over the previous two or three months.

Human leukocyte antigen (HLA)—Proteins that form the major histocompatibility complex (MHC); some common HLA alleles are associated with the development of type 1 diabetes.

Hyperglycemia—High blood sugar.

Hypoglycemia—Low blood sugar.

Insulin—A hormone encoded by the *INS* gene that is required for the metabolism of carbohydrates, fats, and proteins and that regulates blood sugar levels; lack of insulin or insulin insensitivity results in high blood sugar levels and diabetes.

Maternally inherited diabetes and deafness (MIDD)—A rare type of diabetes caused by a mitochondrial gene inherited from the mother.

Maturity-onset diabetes of the young (MODY)—A rare form of diabetes inherited in an autosomal dominant fashion. It is similar to type 2 diabetes but develops before the age of 25.

Oral glucose tolerance test (OGTT)—A diabetes test that measures blood sugar at intervals after drinking a sugary solution.

Single nucleotide polymorphisms (SNPs)—Very small genetic changes (a change in a single nucleotide of DNA) that may be linked to diabetes risk.

Transcription factor—A protein that activates specific genes.

Type 1 diabetes mellitus (T1D)—An autoimmune disorder that generally develops in childhood in which the immune system attacks and destroys insulin-producing beta cells; also called insulin-dependent diabetes mellitus (IDDM).

Type 2 diabetes mellitus (T2D)—A condition in which the body does not properly utilize glucose due to insulin resistance or decreased insulin production; also called non-insulin-dependent diabetes mellitus (NIDDM).

Variable number tandem repeats (VNTRs)—Short repeated DNA sequences; VNTRs flanking the insulin gene may be involved in susceptibility to diabetes.

with diabetes to fungal infections of the skin, nails, female genital tract, and urinary tract.

Diabetic nephropathy is kidney disease that may occur early in diabetes. Patients are prone to kidney damage from severe urinary tract infections and high blood pressure. Late-stage kidney disease may cause symptoms resulting from excessive protein in the urine. These symptoms include swelling around the eyes in the morning, swelling of the legs, unintentional weight gain from

fluid accumulation, poor appetite, fatigue, headache, and frequent hiccups.

After 15 years with diabetes, 80% of patients develop diabetic retinopathy—damage to capillary blood vessels that nourish the retina of the eye—due to the effects of poorly controlled blood sugar. Signs of diabetic retinopathy include decreased visual acuity and floating spots within the field of vision. Cataracts that cloud the lens of the eye develop slowly and painlessly, causing

increasing visual problems. The signs of cataracts include cloudy vision and difficulty with night driving due to glare from bright lights. Both diabetic retinopathy and cataracts can progress to blindness. The best defenses against severe vision loss are early detection and treatment via annual eye examinations, and maintaining control over blood sugar, blood pressure, and blood cholesterol.

Diagnosis

T2D is diagnosed by positive results on any one of the three blood tests, followed by a second positive test on a different day:

- fasting blood glucose test (FGT) with values above 126 mg/dL after eight hours of fasting on two separate occasions
- random (non-fasting) blood glucose values above 200 mg/dL, accompanied by increased thirst, urination, and fatigue, and confirmed with an FTG
- oral glucose tolerance test (OGTT) with above 200 mg/dL two hours after consuming a glucose solution for a diagnosis of diabetes or prediabetes

FGT is the preferred test. This convenient test is most reliably performed in the morning after eight hours of fasting on two separate occasions.

- FGT values of 70–99 mg/dL are considered normal.
- Fasting glucose levels of 100–125 mg/dL may indicate a form of prediabetes called impaired fasting glucose (IFG). Individuals with IFG have are at increased risk of developing T2D in the future.
- A fasting glucose level of at least 126 mg/dL in conjunction with a positive OGTT on a separate testing occasion indicates diabetes.

The OGTT requires fasting for eight hours and then drinking a solution containing 2.6 oz (75 g) of glucose dissolved in water. Blood glucose levels are measured at different times over a three-hour interval. Values below 140 mg/dL are considered normal. Values from 140 to 200 mg/dL may indicate prediabetes. Values over 200 mg/dL in conjunction with a positive FGT on a separate testing occasion indicate diabetes. GDM is diagnosed with the OGTT. Glucose levels are normally lower during pregnancy, so the threshold values for diagnosis are proportionally lower. The presence of two plasma glucose values meeting or exceeding any of the following levels indicates gestational diabetes: a fasting plasma glucose level of 95 mg/dL, a one-hour level of 180 mg/dL, a two-hour level of 155 mg/dL, or a three-hour level of 140 mg/dL.

The hemoglobin A1c (HbA1c) test is used to monitor blood sugar control over a longer period of time.

Controlled blood glucose helps to minimize the development of complications caused by chronically elevated glucose levels, such as progressive damage to body organs. The HbA1c test is an overall picture of the average amount of glucose in the blood over the previous few months. HbA1c is the term for glycosylated (glucose-carrying) hemoglobin in red blood cells. HbA1c can indicate how severe blood sugar fluctuations have been in newly diagnosed patients or may indicate the need for medication or diet adjustments. HbA1c tests may be performed several times per year. The HbA1c test does not reflect temporary acute fluctuations in blood glucose. A 1% change in HbA1c reflects a fluctuation of approximately 30 mg/dL in average blood glucose. An HbA1c value of 6% corresponds to an average blood glucose level of 135 mg/dL, whereas an HbA1c of 9% corresponds to an average blood glucose level of 240 mg/dL. The closer the HbA1c can be kept to 5% or 6%, the better the control and the lower the risk of diabetic complications.

Other tests include the following:

- urinalysis followed by a blood test for ketones and pH to diagnose DKA
- insulin levels
- C-peptide (a byproduct of insulin production) levels
- antibodies against insulin, islet cells in the pancreas, or an enzyme called glutamic acid decarboxylase, which can indicate that a child is at risk for T1D

Treatment and management

The goals of diabetes treatment are to reduce symptoms, prevent diabetes-related complications, and prolong life. General diabetes treatment includes regular doctor visits for an evaluation of general health and neurological function; HbA1c measurements several times a year to evaluate overall blood glucose control; regular evaluation of blood pressure, cholesterol, and triglyceride levels; annual eye examinations; dental examinations and cleaning every six months; daily foot inspection; and current immunizations. Diabetes education is critical to the treatment plan.

The standards of diabetes management are as follows:

- a healthy diet of fruits, vegetables, and whole grains
- physical activity and regular exercise
- monitoring carbohydrate intake
- regular blood sugar monitoring with a home kit or device
- weight control or weight loss if required
- foot care

After a diagnosis of T1D, the immediate goals are to control blood glucose levels and DKA, if present. A sudden onset of severe symptoms may require hospitalization. People with T1D must take insulin daily for life. Insulin is either injected under the skin at specified times using a syringe or administered by an infusion pump that delivers the insulin continuously. Insulin is not available as an oral medication. There are different types of insulin that vary in how quickly they work and the duration of their effects. Different types of insulin are sometimes mixed in an injection. Injections are usually self-administered from one to three times daily. T1D requires that food intake be balanced by insulin intake to prevent extreme fluctuations in blood glucose. Blood sugar must be monitored regularly. Other medications may include the following:

- pramlintide (Symlin) before eating to slow movement of food through the digestive tract and prevent spikes in blood sugar
- high blood pressure medications
- aspirin to protect the heart
- cholesterol-lowering drugs

Hypoglycemia can result from too much insulin, drinking alcohol, overexertion, or eating too little. Symptoms of low blood sugar typically appear when blood glucose levels fall below 70 mg/dL. The treatment is consuming sugar, such as fruit juice. Sugar intake should be continued until blood glucose control is achieved. Only after blood glucose has returned to normal should more substantial food be eaten. Severe hypoglycemia may require a shot of glucagon at a hospital emergency room.

Ketones can be monitored using a simple urine test available at pharmacies. Left untreated, DKA can worsen and cause death. Treatment of DKA involves lowering the blood glucose level to normal and replacing fluids lost through excessive urination and vomiting. It is often possible to recognize the early warning signs of DKA and make appropriate corrections at home before the condition progresses. If severe DKA develops, hospitalization is often required.

T2D can sometimes be controlled with by weight loss, diet, and exercise alone. Medication may include the following:

- metformin—usually the first medication prescribed—to improve insulin sensitivity and lower glucose production by the liver
- sulfonylureas to increase insulin production and secretion
- meglitinides to increase insulin release by the pancreas
- thiazolidinediones to increase insulin sensitivity
- DPP-4 inhibitors to reduce blood sugar
- GLP-1 receptor agonists to slow digestion and lower blood sugar

QUESTIONS TO ASK YOUR DOCTOR

- What is the probability that I or my children will develop diabetes?
- What type of diabetes do I have?
- Which treatments are available for my type of diabetes?
- Can you recommend an organization that can provide additional information about diabetes?
- Is there genetic testing available for diabetes susceptibility genes?

- SGLT2 inhibitors to decrease glucose reabsorption by the kidneys and increase its excretion in the urine
- insulin for some patients

People with T2D and a body mass index (BMI) greater than 35 may be candidates for weight loss (bariatric) surgery. Blood sugar levels usually return to normal after surgery, even before weight loss begins.

Prognosis

Diabetes is a chronic disease for which there is not yet a cure. The prognosis varies based on the degree of blood glucose control. Good control of blood glucose can delay or even prevent the progression of complications and secondary illnesses. Complications may occur even with good blood sugar control, but good control significantly reduces the risks for heart failure, stroke, and death. A reduction of HbA1c by 1% can improve prognosis and decrease the risk of complications by 25%. Prognosis is greatly improved by maintaining a normal BMI. A BMI of 18–24.9 is considered normal and improves diabetes prognosis. A BMI of 25–29.9 indicates overweight, and a BMI of 30 or more indicates obesity and a poor prognosis. People with diabetes have increased susceptibility and a worse prognosis for illnesses such as influenza. Smoking cigarettes significantly worsens diabetes prognosis by increasing the risk of vascular complications, gangrene, and amputations.

Promising research

Although insulin is a lifesaving treatment for many people with diabetes, it is not a cure. Intensive insulin therapy is an effective treatment for the symptoms of diabetes but it also can produce undesirable side effects such as unintended weight gain and increased risk of sharp

drops in blood sugar, which are dangerous and may be life-threatening. Sensitizing beta cells in the pancreas to insulin may protect people with diabetes from beta cell failure. In January 2021, researchers at the Helmholtz Zentrum Muenchen, the Technical University of Munich and the German Center for Diabetes Research identified a novel insulin inhibitory receptor called inceptor. Inceptor is upregulated in diabetes, and by blocking insulin signaling it likely contributes to insulin resistance. In animal studies, blocking the inceptor function in beta cells in the pancreas increased insulin signaling and increased functional beta cells. The researchers hope to use the discovery of inceptor to develop drugs to promote beta cell regeneration and essentially cure diabetes.

Diamond-Blackfan anemia

Definition

Diamond-Blackfan anemia (DBA) is a very rare and potentially life-threatening blood disorder in which the bone marrow does not produce enough red blood cells to carry oxygen to the body. Generally diagnosed in the first year of life, DBA is characterized by unusually pale skin, weakness, fatigue, and irregular heartbeat. In some cases there may also be associated birth defects of the limbs, heart, and palate.

First described in 1938 by two Boston Children's Hospital doctors, Kenneth Blackfan and Louis Diamond, DBA is also known by a number of other names including the following:

- Aase-Smith syndrome II
- Aase syndrome
- Blackfan-Diamond anemia (BDA)

- Blackfan-Diamond disease (BDD)
- Blackfan-Diamond syndrome (BDS)
- chronic congenital agenerative anemia
- congenital erythroid hypoplastic anemia
- congenital hypoplastic anemia of Blackfan and Diamond
- congenital pure red cell anemia or aplasia
- erythrogenesis imperfecta
- hypoplastic congenital anemia
- inherited erythroblastopenia

Description

DBA, like other forms of anemia, results from a decreased amount of oxygen in the blood, which causes symptoms such as weakness, heart murmurs, pale skin, shortness of breath, and an increased risk of developing cancers such as acute myeloid leukemia (AML) and osteosarcoma (a type of bone cancer). While some people with DBA have no physical symptoms, others may have multiple birth defects, including triphalangeal thumb (TPT), a structural abnormality of the thumbs in which the thumbs are formed with three bones like the other fingers rather than two as seen in a typical thumb.

Several other physical abnormalities have been described in individuals with DBA, including narrow shoulders, hypoplastic radius (underdevelopment of one of the bones of the lower arm), heart defect, cleft lip/palate, and late closure of the fontanelles (soft spots on an infant's skull where the bones have not yet fused).

Genetic profile

The available evidence suggests DBA is inherited in an autosomal recessive fashion, meaning that an affected person has two copies of the abnormal gene. Parents of an affected individual carry one abnormal copy of that particular gene, but their other gene of the pair is normal. One copy of the normal gene is sufficient for the parent to be unaffected. If both parents are carriers of a gene for the same autosomal recessive condition, there is a one in four chance in each pregnancy that they will both pass on the abnormal gene and have an affected child.

Mutations in the *RPL5*, *RPL11*, *RPL35A*, *RPS7*, *RPS10*, *RPS17*, *RPS19*, *RPS24*, and *RPS26* genes are known to cause DBA. Responsible for providing instructions for producing ribosomal proteins, these genes are crucial for the creation of cellular structures called ribosomes. Ribosomes create proteins within every cell. Mutations in any of these genes affect the function and longevity of ribosomal proteins. A shortage of ribosomal proteins may cause the blood-forming cells in the bone marrow to die, resulting in anemia. This process of cell

death may also contribute to the other health problems associated with DBA.

In 40% to 50% of individuals with DBA, the exact cause is unknown, while nearly 25% of known DBA cases are caused by mutations in the *RPS19* gene. The remaining 25% to 35% of individuals with DBA have identified mutations in the *RPL5*, *RPL11*, *RPL35A*, *RPS7*, *RPS10*, *RPS17*, *RPS24*, or *RPS26* genes. Researchers suspect additional gene mutations may contribute to the cause of DBA.

Demographics

DBA is a rare condition, affecting approximately five to seven per one million live born infants worldwide. According to the Centers for Disease Control and Prevention (CDC), there are approximately 25 to 35 new cases of DBA identified each year in the United States and Canada. The disorder occurs equally in males and females and across all races and ethnicities.

Signs and symptoms

Congenital hypoplastic anemia (CHA) and abnormal thumbs (TPT) are the two classic signs of DBA. The anemia may require treatment with steroids, or possibly blood transfusions, but tends to improve over time. TPT may cause a person with DBA to have difficulty grasping and manipulating objects with their hands. A hypoplastic radius may complicate problems with appearance and movement of the hands and arms. Narrow and sloping shoulders are caused by abnormal development of the bones in that area of the body.

Slow growth in children with DBA may be partly related to their anemia but is more likely to be genetically predetermined due to the syndrome. Ventricular septal defect (VSD), a hole between the bottom two chambers of the heart, is the cardiac defect reported most often, and several cases of cleft lip and palate have occurred as well.

Diagnosis

DBA is diagnosed by physical examination and lab tests that include the following:

- **Blood tests**—Bloods tests are used to measure the number of red blood cells (reticulocytes and reticulocytes) and a blood count. Diagnosis is confirmed if the red blood cell counts are low in the presence of a normal number of white blood cells and platelets.
- **Bone marrow aspiration**—During this test, fluid is removed from the bone marrow using a long needle. Patients are given local anesthetic and a conscious sedation to help them remain calm and comfortable during the test.

KEY TERMS

Congenital hypoplastic anemia (CHA)—A significant reduction in the number of red blood cells present at birth, usually referring to deficient production of these cells in the bone marrow. Also sometimes called congenital aplastic anemia.

Fontanelle—One of several soft spots on the skull where the developing bones of the skull have yet to fuse.

Hypoplastic radius—Underdevelopment of the radius, the outer, shorter bone of the forearm.

Triphalangeal thumb (TPT)—A thumb that has three bones rather than two.

- Bone marrow biopsy—During a biopsy, the patient is given a local anesthetic and conscious sedation, and marrow cells are removed. This procedure is always performed along with marrow aspiration.
- Genetic screening—Using a blood sample, gene sequencing, gene duplication, and gene deletion testing may be performed. These tests determine whether there are mutations in the genes known to cause DBA and may be helpful in treatment planning.

Treatment and management

Some people with DBA require no medical treatment; however, for individuals who do require treatment, the most common options are oral corticosteroids, blood transfusions, and bone marrow or stem cell transplantation.

Corticosteroids

Corticosteroids are medications used to treat many medical conditions. When taken by people with DBA, corticosteroids will increase red blood cell production in approximately 80% of cases. The dosage is managed closely. Doctors will prescribe just enough corticosteroid to increase the red blood cell count. It generally takes between two to four weeks for the red blood cell count to increase. After a while, this dosage may need to be increased as the patient's body becomes accustomed to the medication.

There are long-term and short-term side effects when taking corticosteroids. Some may be serious. If side effects become a problem, other treatment options may be considered.

The short-term side effects of corticosteroid treatment include the following:

- Behavior changes, difficulty sleeping, and irritability
- Elevated blood pressure
- Increased blood sugar
- Increased risk of pneumonia, thrush (white coating in the mouth), infections, and poor wound healing
- Acne and increased hair growth
- Upset stomach, increased hunger, and water retention
- Weight gain, increased fat on the face, upper back, and stomach

Long-term side effects of corticosteroid treatment include all short-term side effects as well as the following:

- Diabetes
- Eye problems
- Fragile bones and painful hip and shoulder joints
- Muscle weakness
- Poor growth in children, sometimes severe

Blood transfusion

Another treatment for DBA is blood transfusion. In this treatment, blood from a healthy person is injected into another person through a vein or a permanent intravenous (IV) device. The healthy blood increases the number of red blood cells in the person with DBA. Individuals with DBA may need blood transfusions as often as every few weeks or only a few times a year. Some patients may require transfusions regularly for many years. After transfusion, most people with DBA will experience increased energy and will feel better. Blood transfusions for children with DBA may help prevent or treat the decreased growth rates that are a common symptom.

While problems from blood transfusions are rare, some people may experience side effects such as transfusion allergic reaction, infection, abnormal antibody development, or excess iron accumulation in various organs. Allergic reaction to blood transfusion may cause itching, hives, or rash. Very rarely this allergic reaction may be serious, causing wheezing, coughing, and difficulty breathing. If allergic reaction is suspected, patients may be treated prior to transfusion to help prevent complications.

Many people are concerned about the risk of infection from blood transfusion. Blood centers test all blood and make every effort to ensure that blood used in transfusion is safe. Donors are screened, and blood is not accepted from individuals who do not meet donation standards. All blood donations are tested for viral and bacterial infections, and in the United States infections from blood transfusions are extremely rare. In general, the blood supply in the United States is very safe.

Human blood contains traits that make it unique to each individual. When blood from a different person enters the body, the recipient's blood may produce cells, called antibodies, to fight the foreign or unknown blood. These antibodies can destroy the blood from the transfusion. To prevent these antibodies from forming, blood centers work carefully to ensure donor blood matches as closely as possible to recipient's blood.

Excessive iron may accumulate in the organs of individuals who have frequent blood transfusions. Called iron overload, it occurs when iron found in the blood from a blood transfusion enters the body. Excess iron is not easily excreted from the body, and it can accumulate in organs such as the heart, liver, and pancreas. If this condition is not treated, the organs may be damaged. To prevent iron overload, doctors carefully monitor the patient's growth, development, iron levels, hormone levels, and the state of his or her organs. Individuals with DBA who are undergoing blood transfusion should not take any medication or supplements that contain iron. Medication called chelation drugs may be prescribed to help remove excess iron.

A rare but potentially very serious complication of blood transfusion is a condition called hemolysis. Hemolysis occurs when the blood cells from the transfusion begin to die. Antibodies from the recipient's own body may attack and kill the donated blood cells. Symptoms may begin shortly after the transfusion or up to ten days later and may include:

- Fever
- Back or flank pain
- Dark urine
- Pale skin
- Yellow-tinted skin
- Dizziness and/or fainting

If any of these symptoms occur, call a doctor immediately.

Stem cell (bone marrow) transplantation

Stem cell transplant, also called a bone marrow transplant, is a procedure in which healthy stem cells are taken from a donor and given to a person with DBA. Much like a blood transfusion, stem cells enter the body through an IV. Over the course of several weeks, the stem cells migrate to the bone marrow where they begin to make red blood cells. In some cases, DBA may be cured by stem cell transplant.

Stem cells are immature blood cells and are found in bone marrow, blood cells, and umbilical cord blood from a delivered baby. Stem cells for transplantation may come from any of these sources.

QUESTIONS TO ASK YOUR DOCTOR

- What testing do you recommend?
- Which family members should have genetic testing?
- Is anemia a problem for my child?
- What type of physical therapy or exercises should my child do?

Stem cell donors and recipients must have very similar blood. Specifically, the donor's human leukocyte antigen (HLA) type must be the same as the recipient's. HLA helps the body identify blood that belongs and other substances that must be destroyed such as infections. Siblings generally have similar HLA and often make compatible donors. The sibling will have genetic testing for DBA. Siblings with DBA may not donate stem cells. HCL is inherited from each parent; therefore, each sibling has a 25% chance of being an HCL match. If there are no family members who match, a match may be found in the National Marrow Donor Program (NMDP) registry. Non-relative stem cell transplant is not as successful as transplantation from direct family members.

There are risks associated with stem cell transplant. While many patients who have stem cell transplant have few complications, other patients may experience medical problems that require treatment and even hospitalization. Prior to stem cell transplant, the patient must receive chemotherapy and/or radiation therapy to destroy the DBA affected stem cells. This process, called preparative regimen, has side effects consistent with chemo and radiation therapy and may include nausea and vomiting, hair loss, and sores of the mouth and other parts of the body.

After stem cell transplantation, there may be potentially serious side effects, including rejection, infection, and graft-versus-host disease (GVHD). The closer the donor match is to the recipient, the lower the risk of serious side effects and complications.

Rejection, or graft failure, occurs when the recipient's body rejects the donated stem cells. The recipient's immune system may attack the stem cells, killing them. The patient's own stem cells may grow back and the DBA symptoms will return.

Infection may occur, especially soon after the transplant, because the patient's immune system is weakened to help it accept the donated stem cells. Bacteria and viruses from the recipient's own body or from the

surrounding environment may pose a great risk. Infections that might normally be mild can be fatal to patients who have received stem cell transplantation.

Graft-versus-host disease (GVHD) occurs when the stem cells from the donor begin to attack the recipient's body, leading to physical symptoms such as rash, diarrhea, and liver disease. Mild GVHD may be treated with medication; however, in severe cases, it may be fatal.

Management of other features of DBA

Management of problems related to the skeletal abnormalities of DBA may require orthopedic surgery as well as physical and occupational therapy. Heart defects and cleft lip and palate are nearly always correctable, but both require surgery and long-term follow up. A genetic evaluation and counseling should be offered to any individual or couple whose child is suspected of having DBA.

Prognosis

While major medical procedures such as blood transfusions and corrective surgeries may be needed for a child with DBA, the long-term prognosis is generally good. For some patients, effective treatment may completely cure DBA. If a cure is not possible, quality of life may remain high if individuals choose a healthy lifestyle, follow treatment plans, and monitor their health closely. Rarely, treatment options, side effects, and complications may be fatal.

Diastrophic dysplasia

Definition

Diastrophic dysplasia (DTD) is a rare genetic disorder of bone growth and formation that is evident at birth.

Description

Diastrophic dysplasia is one of the genetic osteochondrodysplasias, a group of disorders characterized by abnormal growth and formation of bone and cartilage. Cartilage is a tough, elastic tissue that makes up much of the skeleton during early development. The main features of DTD include: malformed ears, cleft palate, short limbs, short stature, spinal and joint deformities, and abnormalities of the bones of the hands and feet. Although children with DTD may experience delays in motor development (e.g., walking at a later age than expected), they are of normal intelligence. The syndrome derives its name from the Greek word *diastrophos*, meaning "twisted" or "crooked." Maroteaux and Lamy first used the term "diastrophic dysplasia" in 1960 to describe three of their patients and 11 other cases already reported in the literature. Since then, at least 300 cases of DTD have been described. Diastrophic dysplasia is also known as diastrophic nanism or diastrophic dwarfism.

Genetic profile

Diastrophic dysplasia is one of several skeletal disorders caused by mutations in the *SLC26A2* gene (solute carrier family 26, sulfate transporter, member 2), also called diastrophic dysplasia sulfate transporter (DTDST). This gene provides instructions for making a protein that is essential for the normal development of cartilage and for its conversion to bone. Mutations in the *SLC26A2* gene alter the structure of developing cartilage, preventing bones from forming properly and resulting in the skeletal problems characteristic of diastrophic dysplasia. DTD is inherited in an autosomal recessive manner. Affected individuals have a mutation in both copies of their *SLC26A2* gene; they inherit one mutation from each

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Cartilage—Supportive connective tissue which cushions bone at the joints or which connects muscle to bone.

Chondrocyte—A specialized type of cell that secretes the material that surrounds the cells in cartilage.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Clubfoot—Abnormal permanent bending of the ankle and foot. Also called *talipes equinovarus*.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

DNA mutation analysis—A direct approach to the detection of a specific genetic mutation or mutations using one or more laboratory techniques.

Dysplasia—The abnormal growth or development of a tissue or organ.

Epiphysis—The growth area at the end of a bone.

Fibroblast—Cells that form connective tissue fibers like skin.

Founder effect—increased frequency of a gene mutation in a population that was founded by a small ancestral group of people, at least one of whom was a carrier of the gene mutation.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Linkage analysis—A method of finding mutations based on their proximity to previously identified genetic landmarks.

Metacarpal—A hand bone extending from the wrist to a finger or thumb.

Metaphysis—The growth zone of the long bones located between the ends (epiphyses) and the shaft (diaphysis) of the bone.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Nanism—Short stature.

Sulfate—A chemical compound containing sulfur and oxygen.

Vertebra—One of the 26 bones that compose the spine. *Vertebrae* is the plural form.

parent. Parents of affected individuals are carriers; they have a mutation in one copy of their *SLC26A2* gene and are without symptoms of the disorder.

Most bone in the body begins as cartilage and later hardens (ossifies) to form bone. In certain parts of the body such as the rib, auricle, and joints, cartilage does not ossify; it remains as cartilage and functions as load-bearing or shock-absorbing tissue. Cartilage contains sulfur-containing compounds

known as proteoglycans. It is thought that abnormal function of the sulfate transporter gene leads to insufficient sulfate uptake by proteoglycans in the cartilage. This undersulfation results in weakness and distortion of the cartilage. The exact mechanism by which this occurs is not fully understood.

Three other genetic skeletal dysplasias: recessively inherited multiple epiphyseal dysplasia (rMED), atelosteogenesis type 2 (AO-2), and achondrogenesis type IB

(ACG-IB), are also due to mutations in the *DTDST* gene. When compared to DTD, both AO-2 and ACG-1B are more severe skeletal dysplasias, with the latter being a lethal disorder. Recessively inherited MED is a relatively mild condition. This broad range in severity, from mild to fatal, is attributed to the different types and combinations of genetic mutations within the *DTDST* gene that are responsible for these four related diseases.

Demographics

Diastrophic dysplasia is a rare disorder in most parts of the world. The exact incidence is unknown; researchers estimate that it affects about 1 in 100,000 newborns, except in Finland, where the incidence is estimated at 1 in every 30,000 live births. Approximately 1%–2% of Finnish people are DTD carriers. Most Finnish DTD gene carriers possess the same ancestral mutation, known as DTDST (Fin). The high frequency of this single mutation in Finland is attributed to a founder effect.

Signs and symptoms

Diastrophic dysplasia is a variable condition that tends to become more severe with age. Many manifestations of the disorder are prenatal in onset and are therefore apparent at birth.

Growth

Diastrophic dysplasia is considered a short-limbed skeletal dysplasia because the limbs are disproportionately short for the overall height of the individual. The newborn with DTD tends to be short, with an average birth length of 16.5 in. (42 cm). This growth failure continues throughout childhood and is progressive in nature. The degree of deformity caused by orthopedic complications of this disorder can influence overall height. A wide range of final adult heights has been reported with lower limits at 2 ft. 10 in. (86 cm) and 3 ft. 5 in. (104 cm), and upper limits at 4 ft. 5 in. (135.7 cm) and 4 ft. 3 in. (129 cm) for males and females, respectively. On x-ray, the limb bones appear short and thick with broad metaphyses and flattened, irregular epiphyses.

Craniofacial

One of the most distinct features of DTD is the so-called “cauliflower ear.” In more than 80% of infants with DTD, fluid-filled cysts appear on the outer ear (pinnae) during the first few weeks of life. These cysts later calcify and may eventually ossify to form bone. In as many as 25%–60% of individuals with DTD, some form of cleft palate is present. Although individuals with DTD may have a small chin (micrognathia), the head is otherwise normal in size.

Thoracic

Occasionally there may be abnormalities of cartilage in the trachea, larynx, and bronchi, which may lead to a life-threatening complication—collapse of the airways—especially in early infancy.

Spinal

Spina bifida occulta in the neck (cervical) and upper back (thoracic) region is the most common spinal abnormality found in DTD and is present in over 50% of cases. In spina bifida occulta there is incomplete closure of bones of the spinal column. Other common spinal abnormalities include progressive curvature of the spine, either from front to back (kyphosis) or from side to side (scoliosis). Kyphosis in the neck region (cervical kyphosis) is present in at least 30% of affected individuals and is usually evident at birth. This type of spine curvature usually resolves over time without treatment. In severe cases however, cervical kyphosis can lead to respiratory problems. Scoliosis, which is generally not present at birth, may appear at an early age and become problematic in early adolescence. Nearly 50% of females and at least 20% of males will develop scoliosis.

Joints

Joint changes in diastrophic dysplasia are progressive in nature and can be a painful complication of this disorder. Individuals with DTD may experience limited mobility and/or permanent immobility (contractures), especially in the knees and shoulders. The joints in an individual with DTD are also prone to partial or complete dislocations in the shoulders, hips, kneecaps, and elbows.

Hands and feet

The hands of a child with diastrophic dysplasia are distinct. The fingers are short (brachydactyly) and there may be fusion of the joints between the bones of the fingers (sympalangism). The metacarpal bone of the thumb is short and oval-shaped; these bony deformations cause the thumb to deviate away from the hand and assume the appearance of the so-called “hitchhiker thumb,” a classic feature of DTD. The bony changes in the feet are similar to those found in the hands. The great toes may deviate outward, much like the thumbs. Clubfoot deformity (talipes), due to abnormal formation and limited mobility of the bones of the foot, is a common birth defect found in newborns with DTD.

Diagnosis

At birth, the diagnosis of diastrophic dysplasia is based on the presence of the characteristic physical and radiologic (x-ray) findings. DNA mutation analysis may be helpful in confirmation of a suspected diagnosis. In

those rarer cases where DNA mutation analysis does not detect changes, a laboratory test that measures the uptake of sulfate by fibroblasts or chondrocytes may be useful in making a diagnosis.

If there is a family history of diastrophic dysplasia and DNA is available from the affected individual, then prenatal diagnosis using DNA methods, either mutation analysis or linkage analysis, may be possible. DNA mutation analysis detects approximately 90% of *DTDST* mutations in suspected patients. In patients where the mutations are unknown or undetectable, another DNA method known as linkage analysis may be possible and, if so, it can usually distinguish an affected from an unaffected pregnancy with at least 95% certainty. In linkage analysis, DNA from multiple family members, including the person with DTD, is required. DNA-based testing can be performed through chorionic villus sampling or through amniocentesis.

If DNA-based testing is not possible, prenatal diagnosis of diastrophic dysplasia in an at-risk pregnancy may be made during the second and third trimesters through ultrasound. The ultrasound findings in an affected fetus may include: a small chin (micrognathia), abnormally short limbs, inward (ulnar) deviation of the hands, the “hitchhiker” thumb, clubfoot, joint contractures, and spinal curvature.

General population carrier screening is not available, except in Finland where the frequency of a single ancestral mutation is high.

Treatment and management

There is currently no treatment that normalizes the skeletal growth and development in a child with diastrophic dysplasia. The medical management and treatment of individuals with DTD generally requires a multidisciplinary team of specialists that should include experts in orthopedics. At birth it is recommended that a neonatologist be present because of the potential for respiratory problems. Surgery may be indicated in infancy if congenital abnormalities such as open cleft palate and/or clubfoot deformity are present. Throughout childhood and adulthood, bracing, surgery, and physical therapy are measures often used to treat the spinal and joint deformities of DTD. Such measures, however, may not fully correct these deformities.

Due to the significant short-limbed stature associated with diastrophic dysplasia, certain modifications to home, school, and work environments are necessary in order for a person with DTD to perform daily tasks. Occupational therapy may help affected individuals, especially children, learn how to use assistive devices and to adapt to various situations.

QUESTIONS TO ASK YOUR DOCTOR

- What tests are available to determine whether or not our newborn child has diastrophic dysplasia?
- If the child has the condition, what early treatments should be provided to reduce the severity of the disorder?
- As the child grows older, will he or she need to be concerned about transmitting this condition to his or her own children?
- Will our child need to be monitored for this condition throughout his or her life, and, if so, what specific conditions should we watch for?

Prognosis

In infancy there is an increased mortality rate as high as 25%, due to respiratory complications caused by weakness and collapse of the cartilage of the wind pipe (trachea) and/or the voice box (larynx), conditions which may require surgical intervention. Some forms of cleft palate and micrognathia may be life-threatening in early life as they can result in respiratory obstruction. Severe spinal abnormalities such as cervical kyphosis may also cause respiratory problems. After the newborn period, the lifespan of an individual with DTD is usually normal, with the exception of those cases where spinal cord compression occurs as a result of severe cervical kyphosis with vertebrae subluxation. Spinal cord compression is a significant medical problem that can lead to muscle weakness, paralysis, or death. In a susceptible individual, spinal cord compression may occur for the first time during surgery due to the hyperextended neck position used during intubation. Other anesthetic techniques may be indicated for such cases.

People with diastrophic dysplasia are of normal intelligence and are able to have children. Since many of the abnormalities associated with DTD are relatively resistant to surgery, many individuals with DTD will have some degree of physical handicap as they get older. They may continue to require medical management of their spinal and joint complications throughout adult life.

Direct-to-consumer genetic testing

Definition

Direct-to-consumer (DTC) genetic testing, also called at-home genetic testing, consumer-initiated genetic testing, direct-access genetic testing, and home DNA testing, is an elective (optional) test marketed directly by private companies to the general public. A DTC test can be ordered online or purchased in a store, and completed by anyone over the age of 13 without having to consult a health care provider. DTC testing intended to answer questions about family history is known as ancestry or genealogy testing.

Description

History

The first DTC genetic tests were marketed within a few years after the completion of the Human Genome

A direct-to-consumer genetic testing kit. The purchaser puts a saliva sample in the plastic tube and sends it to the company for analysis. (Martin Shields/Science Source)

Project in 2003. These initial tests were expensive, costing about \$1,000 in 2007. Advances in sequencing technology led to price reductions: the average price of a DTC test dropped to \$400 by 2010; to \$99 by 2012; and as low as \$59 by 2018. In turn, the drop in price prompted growing consumer interest in these tests: the *MIT Technology Review* reported in 2019 that as many people purchased DTC genetic tests in 2018 as in all previous years combined.

By 2018, over 26 million people worldwide had purchased these tests, with the figure projected to rise to 100 million by the end of 2021. Some geneticists estimate that so many DTC tests have been completed in the United States that even people who have not taken such a test are likely to be related genetically to someone who has.

DTC marketing and regulation

Direct-to-consumer genetic tests were initially not regulated by the Food and Drug Administration (FDA) or any other federal agency, as they were marketed by private companies and so were purely commercial transactions. In 2006, however, the U.S. Government Accountability Office (GAO) began an investigation of the companies that offered DTC genetic tests, and found that the results of the tests were often misleading and marketing practices were sometimes deceptive. As a result, the FDA redefined DTC genetic tests in 2010 as medical devices requiring the agency's approval. In 2013, the FDA sent cease-and-desist letters to companies marketing DTC genetic tests. By 2015, however, the largest companies began to redefine their tests and sought FDA approval for them as medical devices. As of 2021, the only company with FDA approval for its DTC genetic tests is 23andMe. The

FDA has approved the company's tests for genetic health risk (GHR) testing, carrier screening, and cancer predisposition tests. The FDA does not currently regulate ancestry tests or low-risk general health tests.

How the tests work

People who are interested in a DTC genetic test can purchase most brands over the counter in drugstores or they can order their kit online from a test company's website. As of 2021, the two largest DTC genetic test companies by far are Ancestry and 23andMe; others include Orig3n, HomeDNA, MyHeritage, and African Ancestry.

To use the kit, the person provides a saliva sample or a buccal swab (skin cells obtained by wiping the inside of the cheek with a Q Tip) and then returns the kit to the company for analysis. A few companies ask the consumer to submit a blood sample drawn at a health clinic. To keep costs down, DTC testing companies use automated analysis of a preplanned number of single-nucleotide polymorphisms (SNPs), which are genetic variants characterized by a substitution of a single nucleotide at a specific position in a person's genome. SNPs can be used to identify a person's susceptibility to such genetic disorders as sickle cell anemia or cystic fibrosis. However, the SNP arrays used by the company can identify only the particular gene variants included on its array.

After performing the analysis, the company typically notifies the consumer in the form of an online report on the company website, although some companies will also notify consumers by a telephone call or by mail. DTC genetic companies vary as to whether their fee includes a genetic counselor's explanation of the test results or answers to the consumer's questions. Some companies provide these services; others do not, and it is up to each consumer to find out the specific services offered before purchasing and using a kit.

If the company does not offer explanation of test results as part of the cost of its kit, consumers have the option of consulting so-called third-party interpretation (TPI) services online to obtain an analysis of their genomic data. They can also consult their primary care physician or a qualified genetic counselor for guidance in understanding the data.

Purpose

People may be interested in DTC genetic testing for several reasons:

- Curiosity about their family's history, ethnicity, and countries of origin.
- Concern about susceptibility to various diseases. Some DTC tests offer estimates of a person's risk of such disorders as Alzheimer's, Parkinson's, or celiac disease.

- Carrier risk. In genetics, a carrier is a person who has a mutation for a specific disease and is capable of passing it on to descendants. The carrier will not necessarily have symptoms of the disease in question.
- Paternity testing.
- Kinship identification. Some people are interested in finding out whether they have previously unknown relatives or are related to a famous person. Adoptees and people conceived by in vitro fertilization (IVF) are increasingly interested in locating their biological parents, including sperm donors. According to recent studies, women are four times more likely than men to look for relatives identified by DTC genetic testing.
- Desire to improve one's overall health and fitness by making lifestyle changes on the basis of genetic test results.
- Pharmacogenomic information. Some DTC genetic tests offer information about the ways in which a person's genome may affect his or her response to prescription drugs.

Although most DTC genetic testing companies focus only on human DNA, HomeDNA offers three genetic testing kits for dogs and cats: a mixed-breed dog identification test; a dog DNA health screen, and a cat DNA health screen. Each test costs \$125 as of 2021.

Limitations

The chief limitation of DTC genetic testing is that it cannot be used to definitively diagnose or treat a specific disease or condition. Consequently, most insurance companies will not pay for DTC tests, and the results of DTC genetic testing cannot be used as evidence in a court of law. As noted earlier, these tests offer only restricted sets of SNPs for analysis; DTC tests may include only some of the genes, regions of genes, or variants relevant to a specific disease.

In addition, the genes sampled by DTC tests are not the only factors contributing to a person's health risks. Such factors as genetic variations that were not tested by the company; environmental, occupational, and climate-related issues; and lifestyle choices like diet, exercise, drug use, and sexual behavior also influence a person's risk of developing diseases.

Risks

There are several risks associated with DTC genetic tests:

- Potentially inadequate oversight of the company's laboratory. The Clinical Laboratory Improvement Amendments (CLIA) of 1988 is a set of federal standards regulating laboratory testing in the United

KEY TERMS

Autosome—Any chromosome that is not a sex chromosome. The human genome has 22 pairs of autosomes.

Buccal—Related to the cheek.

Carrier—In genetics, a person who has a genetic mutation associated with a disease and is capable of passing it on. A carrier may or may not display the symptoms of the disease.

Clickwrap agreement—An online agreement between a user and a company in which users must click a box or button and read the agreement before they download content, make a purchase, or use a website.

Clinical Laboratory Improvement Amendments (CLIA)—A set of regulations passed in 1988 that establish federal standards applicable to all laboratories or sites that test human specimens for health assessment or to diagnose, prevent, or treat disease.

False negative—A test result that indicates that a disease or condition is not present when it really is; sometimes called a type II error.

False positive—A test result that indicates that a person has a disease or condition when they do not; it is sometimes called a type I error.

Forensic—Pertaining to the use of science or medicine in the investigation and establishment of evidence in a court of law.

Genealogy—The study or investigation of a person's lineage or family tree.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Germline—The population of a complex organism's cells that pass on genetic information to offspring. Germline cells include eggs, sperm, and fertilized eggs.

Health Insurance Portability and Accountability Act (HIPAA)—A 1996 federal statute that includes a privacy rule regulating the use and disclosure of protected health information (PHI). DTC genetic testing is not subject to HIPAA privacy regulations.

In vitro fertilization (IVF)—A form of assisted reproduction technology in which a human ovum (egg) is combined with sperm outside the body in a laboratory container ("in vitro" means "in glass").

Pharmacogenomics—The study of the ways in which a person's genetic makeup affects his or her response to drugs.

Single nucleotide polymorphism (SNP)—A germline substitution of a single nucleotide (any of a group of molecules that form the building blocks of DNA or RNA) at a specific position in a person's genome.

Third-party interpretation (TPI) service—An online tool that analyzes the raw DNA data from a DTC genetic test and provides a genetic health risk report.

States. They require clinical laboratories to be certified by the Center for Medicare and Medicaid Services (CMS) before accepting human samples for diagnostic testing. The FDA categorizes laboratory tests as high complexity, moderate complexity, or waived. The FDA waives CLIA certification for tests approved for home use, which means that DTC genetic tests may be analyzed in laboratories that have not been certified by CMS.

- **False negatives.** A false negative is a test result that indicates that a disease or condition is not present when it actually is. Because DTC genetic tests are based on limited arrays of SNPs, it is possible for a person to have a health condition that is not detected by a particular company's SNP array.
- **False positives.** A false positive is an error in which a test result incorrectly indicates the presence of a disease that is not actually present. This type of error means that a DTC test report can show that the consumer has an

increased risk of a serious health condition when that risk really does not exist. False positives can cause considerable anxiety in consumers of DTC testing, leading to what one group of researchers considers a burden on the health care system, with clinical testing done in order to confirm that a patient does not have a clinical diagnosis of the disease associated with the reported genetic variant.

- **Disagreement among geneticists and researchers** about the significance of some genetic variants and their roles in causing disease. In regard to DTC testing, one DTC testing company may classify some SNPs as disease-causing or disease-associated variants, while another may classify them as benign.
- **Family disruption related to the exposure of secrets.** An increasing number of people are discovering that their legal father is not their biological father; that they have half-siblings that they were unaware of due to a parent's extramarital affair; or that they may have as many as a

hundred relatives as the result of IVF conception via a sperm donor. One such donor, a biochemist living in the United Kingdom, is known to have fathered over 100 children. In addition, adoptees using DTC genetic testing in order to track down their biological parents may encounter rejection rather than acceptance.

- **Personal identity issues.** Some people who had a specific self-understanding based on a particular ethnic identity or geographical origin may feel disoriented or disappointed if their DTC test does not confirm their self-image. One recent example concerns a woman who thought that she was a mixture of Scots-English and German ancestry, only to find out that she had numerous biological connections to Hispanics in the company's database.
- **Privacy concerns.** By far the greatest risk confronting people who take a DTC genetic test is the high probability that they are signing away their right to privacy of their DNA. DTC genetic testing is not covered by the Health Insurance Portability and Accountability Act (HIPAA) of 1996. Most DTC testing companies have what is known as a clickwrap agreement, in which a consumer purchasing a test kit online must press or click on a button in order to read the agreement and complete the purchase. The agreement usually spells out the company's privacy policy, such as who is the legal owner of the data; whether the company will destroy the genetic sample after analysis; whether the company shares or sells data to biotechnology companies, academic institutions, or other organizations; how the company protects consumers' information against unauthorized access; and whether the company will notify consumers of changes in, or updates to, its privacy policy. Anyone purchasing a DTC test kit should read the agreement very carefully before completing their purchase.

Alternatives

The primary alternative to DTC genetic testing is a traditional genetic test, ordered and interpreted by a physician or other health care professional for a specific medical reason. This type of testing is considerably more expensive than DTC genetic testing, costing between \$1,000 and \$2,000 as of 2021. A clinical genetic test involves a full investigation into the genetic cause of a disease, which sometimes includes using more than one sequencing method, examining the complete coding regions of the genes in question, and manual investigation rather than automated analysis of gene variants. In addition, a clinical genetic test must be performed in a CLIA-certified laboratory. In spite of the high cost, the results of such tests are considerably more likely to provide an accurate diagnosis, to be specific to the patient

QUESTIONS TO ASK YOUR DOCTOR

- What is your opinion of direct-to-consumer genetic testing?
- How many of your patients have asked you for a clinical genetic test on the basis of DTC test results?
- If I decide to purchase a DTC genetic test, will you help me interpret the results?
- Have you ever referred a patient to a certified genetic counselor on the basis of DTC test findings?

in question, and to guide treatment if a genetic disorder is revealed.

Applications

Research

The explosion of interest in DTC genetic testing and the corresponding increase in the number of consumers distressed by test results has led to one NIH-registered clinical trial of a tool to assist parents in telling children conceived by IVF about their genetic heritage. Another recently completed clinical trial is a study of how individual patients and their physicians understand and respond to uncertain genetic risk information obtained by DTC testing.

Forensic investigation

The growing popularity of DTC genetic testing has allowed for the compilation of large databases of genetic information about people living in the United States. GEDmatch is a company founded in 2010 to compare autosomal DNA data files from different testing companies in order to assist amateur genealogists as well as adoptees searching for birth parents. As of late 2020, GEDmatch held over 1.45 million DNA profiles. The company made history in 2018 when its databank was used to track the Golden State Killer, a serial rapist and murderer who had been unidentified since his crime spree began in 1973. At least 10 other cold homicide cases have been solved by using GEDmatch since 2018.

The other significant forensic application of the DNA data compiled by GEDmatch is identification of missing persons and other unknown human remains. The DNA Doe Project was established in 2017 to help identify such persons. At least 42 persons, some of whose

remains were discovered as early as 1971, have been positively identified by the Doe Project as of early 2021.

Disorders of sex development (DSD)

Definition

Hermaphroditism, also called intersex, is a rare condition in which ovarian and testicular tissue exist in the same person. When the tissue is a mix of ovarian and testicular tissue it is referred to as an ovotestis. The testicular tissue contains seminiferous tubules or spermatozoa. The ovarian tissue contains follicles or corpora albicantia. The condition is the result of a chromosome anomaly.

Description

Among human beings, hermaphroditism is an extremely rare anomaly in which gonads for both sexes are present. External genitalia may show traits of both sexes, and the chromosomes show male–female mosaicism (where one individual possesses both the male XY and female XX chromosome pairs). There are two different variants of hermaphroditism: true hermaphroditism and pseudohermaphroditism. There are female and male pseudohermaphrodites. True hermaphroditism refers to the presence of both testicular and ovarian tissue in the same individual and is classified by the position and histology of the testes/ovaries. In 30% of cases there is a testis on one side with an ovary on the other, in 50% of cases there is both testicular tissue and ovarian tissue on both sides, and in the remaining 20% of cases there is an ovotestis on one side and either a testis or an ovary on the other side. The external genitalia in these individuals may range from normal male to normal female. However, most phenotypic males have hypospadias. Pseudohermaphroditism refers to gonadal dysgenesis.

Genetic profile

The most common karyotype for a true hermaphrodite is 46XX (70% of cases). DNA from the Y chromosome is translocated to one of the X chromosomes. Clinical studies have shown cases in which molecular analysis shows the sex-determining region (*SRY*) gene to be present with a microdeletion of other major regions on the Y chromosome. If this is the case, the patient is a phenotypical male but a karyotypical female. The karyotype for male pseudohermaphrodites is 46XY. Female pseudohermaphroditism is more complicated. The condition is caused by deficiencies in the activity of enzymes. The genetic basis for three enzyme deficiencies has been

identified. Deficiency of 3B-hydroxysteroid dehydrogenase type 2 is due to an abnormality on chromosome 1p13.1. Deficiency of 21-hydroxylase is due to an abnormality on chromosome 6p21.3. Deficiency of 11B-hydroxylase type 1 is due to an abnormality on chromosome 8q21.

Demographics

True hermaphrodites are extremely rare, representing only about 5% of all disorders of sexual dysmorphia, and are found more commonly in Africa. Approximately 500 individuals have been identified in the world to date. Because of the ambiguity of genitalia and difficulties in making an accurate diagnosis, the incidence of pseudohermaphroditism is not well established. The incidence of male pseudohermaphroditism has been estimated at between 3 and 15 per 100,000 people. The incidence of female pseudohermaphroditism has been estimated at between 1 and 8 per 100,000 people.

Signs and symptoms

True hermaphroditism is characterized by ambiguous internal and external genitalia. On internal examination (most often using laparoscopy), there is microscopic evidence of both ovaries and testes. Male pseudohermaphroditism is characterized by ambiguous internal and external genitalia. However, gonads are often (but not always) recognizable as testes. These are frequently softer than normal. An affected person is often incompletely masculinized. Female pseudohermaphroditism is characterized by female internal genitals. External genitals tend to appear as masculine. This is most commonly characterized by clitoral hypertrophy. Most hermaphrodites are infertile, although a small number of pregnancies have been reported.

Diagnosis

True hermaphroditism is often diagnosed after laparoscopic investigation. An initial suspicion of male pseudohermaphroditism is often made by inspection of external genitals during childhood and by MRI findings, which may show a mix of internal reproductive organs. Palpation of testicles and prostate oftentimes presents with dysmorphia or amorphia. The descent of the testis is dependent on the amount of testicular tissue present in the body, also an indicator of hermaphroditism. Hermaphroditism is confirmed by chromosomal analysis and assays of hormones such as testosterone, follicle-stimulating hormone, and luteinizing hormone. Initial suspicion of female pseudohermaphroditism is also made by inspection of external genitals. This is confirmed by analysis of chromosomes and hormonal assay.

QUESTIONS TO ASK YOUR DOCTOR

- Should I consider hormone replacement therapy?
- What are the chances that another child of mine will have this abnormality?
- Are there support groups for me/my child?
- How often should I/my child see a medical doctor?
- Am I/my child a surgical candidate?

Laparoscopic examination usually reveals nearly normal female internal genitals.

Treatment and management

Early assignment of gender is important for the emotional well-being of any person with ambiguous genitalia. A decision to select a gender of rearing is usually based on the corrective potential of the ambiguous genitalia rather than by using chromosome analysis.

Corrective surgery is used to reconstruct the external genitalia. In general, it is easier to reconstruct female genitalia than male genitalia, and the ease of reconstruction plays a role in selecting the gender of rearing. Treating professionals must be alert for stress in persons with any form of hermaphroditism and their families.

Prognosis

With appropriate corrective surgery, external genitalia may appear normal. However, other problems, such as virilization, may appear later in life. There has been some interest among persons with ambiguous genitalia at birth to reverse their gender of rearing.

DNA (deoxyribonucleic acid)

Definition

Deoxyribonucleic acid (DNA) is the molecule that contains the hereditary information. It is found in almost all of the cells of humans and other organisms. Most DNA is located in the nucleus of cells and is referred to as nuclear DNA. A small amount, called mitochondrial DNA (mtDNA), is in the mitochondria, the energy-producing organelles inside cells. DNA stores all the instructions required for making proteins, the fundamental components of an organism's cells, including structural proteins, enzymes, hormones, and antibodies and other immune-system proteins, that are necessary to maintain life. The complete set of nuclear DNA of a cell or organism is called its genome.

The information carried by DNA is in chemical form: DNA molecules consist of two twisting paired strands or helices. Each strand contains four types of chemical compounds called deoxyribonucleotides, consisting of a sugar, a phosphate group, and one of four bases—adenine (A), thymine (T), guanine (G), or cytosine (C). Each chain is

formed by the linked sugar-phosphate groups on the outside of the helix. The bases of each chain face inside of the helices and form specific base pairs joining the two chains—an A always pairs with a T, and a C always pairs with a G. The order (sequence) of these bases determines their biological instructions.

Each DNA sequence that contains a set of instructions (for example, instructions for making a specific protein) is known as a gene. The sizes of genes can vary greatly, ranging from about 1,000 paired bases to one million paired bases in humans. Altogether, the human genome contains about three billion base pairs, which are organized into the 23 pairs of chromosomes within the nuclei of almost all human cells. The DNA is tightly coiled and packaged into the chromosomes. When cells divide, the DNA unwinds and is copied (transcribed), and the copies are transferred to the new cells. DNA also unwinds when its instructions are required to make proteins and for other biological processes.

The history of DNA

Genetics is the science of heredity—the study of the structure and function of genes and the methods by which genetic information contained in genes is passed from one generation to the next. The modern science of genetics can be traced to the research of Gregor Mendel, who developed laws that mathematically describe how hereditary characteristics are passed from parents to offspring. These laws revealed that hereditary characteristics are contained in discrete units of genetic material now known as genes.

The story of genetics during the twentieth century is, in one sense, an effort to discover the gene itself. An important breakthrough came in the early 1900s with the research of the American geneticist, Thomas Hunt Morgan (1866–1945). Working with fruit flies, Morgan was able to show that genes are associated with the chromosomes in the nuclei of cells. By 1912, Hunt's student,

Structure of DNA molecule (Gale)

the geneticist Alfred Sturtevant (1891–1970), had constructed the first chromosome map showing the relative positions of different genes arranged linearly on a chromosome. Genes, therefore, had concrete physical references as positions on a chromosome.

During the 1920s and 1930s, a small group of scientists looked for a more specific description of the gene by focusing on its molecular composition. Most researchers assumed that genes were proteins, because proteins are large and complex and can occur in an almost infinite variety of structures. These were qualities expected for a class of molecules that must be able to carry the enormous variety of genetic traits.

A smaller group of researchers looked to a second family of compounds as potential candidates for the molecules of heredity—nucleic acids. Nucleic acids were first discovered in 1869 by the Swiss physician Johannes Friedrich Miescher. Miescher originally called these compounds “nucleins” because they were obtained from the nuclei of cells. One of Miescher’s students, Richard Altmann, later suggested a new name for the compounds that better reflected their chemical nature: nucleic acids.

In the 1930s, nucleic acids seemed unlikely candidates for molecules of heredity. What was known about their structure suggested that they were too simple to carry the vast array of complex information required for a molecule of heredity. Each DNA molecule consists of a long chain of nucleotides—alternating sugars and phosphates, with the sugars attached to one of the four different nitrogen bases. A fifth pyrimidine base, uracil (U), replaces thymine in ribonucleic acid (RNA). At the time, it was not clear how this relatively simple structure could assume enough different conformations to “code” for hundreds of thousands of genetic traits. In comparison, a single protein molecule contains various arrangements of about 20 fundamental units (amino acids), making it a much better candidate for the carrier of genetic information. However, in the 1940s and early 1950s, elegant experiments demonstrated unequivocally that DNA, not protein, is the genetic material.

The DNA double helix

But how could a simple molecule like DNA carry all of the necessary information? Although the building blocks of DNA—the deoxyribonucleotides—had been known for almost 100 years, their arrangement into a three-dimensional structure remained a mystery. That mystery was solved by a somewhat unusual pair: James Watson (1928–), a 24-year-old American trained in genetics, and Francis Crick (1916–2004), a 36-year-old Englishman, trained in physics and self-taught in chemistry. The two met at the Cavendish Laboratory of

Cambridge University in 1951. They were united by a passionate belief that the structure of DNA held the key to understanding how genetic information is stored in a cell and transmitted to daughter cells and subsequent generations.

The key to the structure of DNA lay in a technique known as x-ray crystallography. When x-rays are directed at a crystal of some material, such as DNA, they are reflected and refracted by the atoms that make up the crystal. The refraction pattern thus produced consists of a collection of spots and arcs. A skilled observer can determine from the refraction pattern the arrangement of atoms in the crystal. However, obtaining satisfactory x-ray patterns from crystals is often difficult. Interpreting the x-ray patterns—especially for complex structures like DNA—can be extremely difficult.

Watson and Crick were fortunate in obtaining access to some of the best x-ray diffraction patterns that then existed. These “photographs” were the result of work being done by Maurice Wilkins (1916–2004) and Rosalind Elsie Franklin (1920–1958) at King’s College in London. When Wilkins showed Watson one of Franklin’s x-ray patterns, he suddenly saw the solution to the DNA puzzle. Racing back to Cambridge, Watson convinced Crick to make an all-out attack on the DNA problem. They worked continuously for almost a week. Their approach was to construct Tinkertoy-like models of the DNA molecule, shifting atoms around into various positions, looking for an arrangement that would yield the x-ray pattern that Watson had seen in Franklin’s laboratory. A crucial clue came from rules formulated by Erwin Chargaff (1905–2002) and his colleagues at Columbia University in the late 1940s: the base composition (the numbers of As, Ts, Gs, and Cs) of DNA is always the same in cells from a given organism but varies from species to species; and most significantly, the number of As always equals the number of Ts, and the number of Gs always equals the number of Cs.

On March 7, 1953, Watson and Crick found their answer. They built a model consisting of two helices (corkscrew-like spirals) wrapped around each other. Each helix consisted of a backbone of alternating sugar and phosphate groups. To each sugar was attached one of the four nitrogen bases, A, C, T, or G. The sugar-phosphate backbones formed the outside of the DNA molecule, with the nitrogen bases tucked inside. Each nitrogen base on one strand of the molecule faced another nitrogen base on the opposite strand of the molecule. The base pairs were not arranged at random, however, but in such a way that each A was paired with a T and each C with a G. The Watson-Crick model immediately suggested how DNA could function as the carrier of genetic information. The sequence of the nitrogen bases along

the molecule could act as the genetic code. A sequence, such as A–T–A–C–G–C, and so on, might tell a cell to make one kind of protein (such as one that makes red hair), whereas another sequence, such as G–C–T–C–T–C, and so on, might code for a different protein (such as one that makes brown hair). Furthermore, the double helix could be unwound to allow for the exact copying of the complementary strands when the chromosomes were duplicated at cell division. At their local pub that night, Watson announced that they had “discovered the secret of life.” Watson, Crick, and Wilkins shared the 1962 Nobel Prize in Physiology or Medicine (Franklin had died in 1958).

Over the next decade, Marshall Nirenberg and his colleagues demonstrated that the sequence of each three bases in DNA coded for a specific amino acid in a protein—known as the “triplet code.” It was further demonstrated that DNA in the nucleus of a cell acts as a template for the formation of mRNA. The mRNA then leaves the nucleus, migrating to the cytoplasm where it acts as a template for the production of protein. The information contained in the mRNA molecule is translated into the “language” of amino acids, the building blocks of proteins, telling the cell’s protein-making machinery the precise order in which to link the amino acids to produce a specific protein.

Forms of DNA

DNA can exist in different forms. The Watson-Crick double helix is a right-handed helix known as the “B” form: the helix makes a turn every 3.4 nanometers (nm), and the distance between two neighboring base pairs is 0.34 nm, yielding about ten base pairs per turn of the double helix. The intertwined strands make two grooves of different widths, called the “major groove” and the “minor groove,” which facilitate the binding of specific proteins. In a solution with higher salt concentrations, DNA can change to the “A” form, which is still right-handed but makes a turn every 2.3 nm, with 11 base pairs per turn. The “Z” form of DNA derives its name from its zigzag shape. It forms a left-handed helix. Although Z–DNA was first identified in synthetic DNA prepared in the laboratory, it has since been found to occur naturally in cells in small amounts. Its biological role in cells is still being elucidated.

Complementary DNA (cDNA) is generated from mRNA in a reaction catalyzed by reverse transcriptase enzymes that come from RNA viruses. These are viruses that have RNA as their genetic material instead of DNA, and they use reverse transcriptase to make DNA to incorporate into the genome of host cells. Using mRNA as a template, scientists can use reverse transcriptase to make cDNA, which can be cloned to create a cDNA library that

KEY TERMS

Amino acids—Building blocks of proteins; 20 different amino acids are coded for by human DNA.

Complementary DNA (cDNA)—DNA that is transcribed (copied) from messenger RNA using the enzyme reverse transcriptase.

Epigenome—All of the molecules that are added to DNA molecules to regulate the activity of genes without changing the DNA sequence.

Genome—The entire DNA sequence of a cell or organism.

Human Genome Project (HGP)—An international collaboration begun in 1990 and completed in 2003 that sequenced the entire DNA sequence of the human genome.

Messenger RNA (mRNA)—The nucleic acid that is transcribed from the DNA of genes and used as the blueprint for proteins.

Mitochondrial DNA (mtDNA)—A small set of genes within mitochondria (the powerhouses of cells) that are maternally inherited.

Nucleotides—The building blocks of nucleic acids (deoxyribonucleotides in DNA and ribonucleotides in RNA), consisting of a sugar, phosphate, and nitrogen base—adenine (A), guanine (G), cytosine (C), or thymine (T)—in DNA.

Polymerase chain reaction (PCR)—A method for making millions of copies of (amplifying) a DNA sequence.

Proteins—The enzymes and structural components of the human body, made up of amino acids; DNA sequences encode the instructions for making proteins.

Single nucleotide polymorphisms (SNPs)—Common variations in single nucleotides in a DNA sequence.

represents the DNA that has been converted into mRNA and protein in cells, tissues, or organisms. This is important because only about 1% of the DNA in the human genome encodes proteins, and only a small percentage of these proteins are produced in a given type of cell or tissue.

A scientific revolution

The discovery of the structure and function of DNA ushered in scientific advances unprecedented in human

history. In 1977, Frederick Sanger developed a method of rapidly determining DNA sequences from various organisms, including humans. In 1981, the first complete genome sequence, other than viral sequences, was announced—the complete human mitochondrial genome sequence. By 1983, scientists had located the DNA that caused Huntington’s disease—the first genetic disorder to be mapped. Another technological advance in 1983, the invention of the polymerase chain reaction (PCR), enabled scientists to make millions of copies of DNAs for sequencing and cloning. By 1989, the first DNA mutation (change) that caused cystic fibrosis had been identified.

The Human Genome Project (HGP) began in 1990. This international collaboration set out to determine the sequence of all three billion base pairs of DNA in the human genome. The first draft of the human genome was published in 2001, and the project was completed in 2003, several years ahead of schedule, due to the development of new sequencing methods (next-gen sequencing). The HGP brought many surprises. For example, instead of the predicted 50,000–140,000 genes in the human genome, there were only about 20,500. In part, this is because the hypothesis that each gene coded for one enzyme (or protein), first proposed by George Beadle (1903–1989) and Edward Tatum (1909–1975) in 1941, turned out to be a gross oversimplification. Modifications to DNA, mRNA, and proteins, as well as numerous regulatory factors, can result in single genes producing different proteins. Furthermore, before the HGP, it was assumed that most of the 99% of the human genome that did not code for proteins is “junk DNA.” The ENCODE Project, an international follow-up to the HGP, has revealed that more than 80% of this non-protein-coding or non-gene DNA is essential for regulating gene expression (protein production by genes).

The HGP and next-gen sequencing have made it relatively simple to identify genes and mutations that cause genetic disorders or that make people susceptible to specific diseases, as well as to screen for mutations and diagnose disorders. These advances have also enabled researchers to study genetic variations among individuals and populations. Another scientific collaboration, the International HapMap Project (for “haplotype map”) is cataloging common genetic variations called single nucleotide polymorphisms (SNPs). These are changes in the nucleotides (A, C, T, or G) at specific locations in the human genome that can be used to identify populations and individuals. The genome contains about ten million SNPs. The HapMap Project is accelerating knowledge of the relationships between genetic differences and human diseases. Yet another large

collaboration has mapped human epigenomes. The epigenome is a collection of modifications to DNA that do not change the DNA sequence but that can affect the protein-producing activity of genes in health and disease. In February 2015, researchers published 111 different epigenomes from different human cell types. One goal of these studies is to discover how genetic differences affect individual responses to drugs (pharmacogenomics) and environmental factors such as toxins. It is hoped that this will lead to precision medicine, in which disease treatments are tailored to an individual’s genetic makeup, as well as environmental and lifestyle factors.

In addition to rapidly sequencing the DNA of people from around the world, scientists have learned to obtain and sequence ancient DNA from humans who lived tens of thousands of years ago. This has had a dramatic effect on ideas about the evolution of modern humans and their migration around the world. For example, it is now clear that modern humans interbred with Neanderthals and possibly other early humans, with 3%–6% of the human genome inherited from Neanderthals.

The synthesis of DNA in the laboratory also has important ramifications. Scientists have been able to design and synthesize new forms of living bacteria. DNA structures are being used to produce various synthetic products, and DNA information-coding functions are being exploited for new methods of data storage.

DNA methylation

Methyl groups (CH₃) are enzymatically added to DNA molecules naturally in the process of methylation without changing the genetic code or genetic sequence of the DNA molecule. This methylation represses transcription of nearby promoters and can change transcriptional patterns between individuals, tissue types, cell types, or health states. Methylation is essential in animal development, and DNA methylation signatures change over time. The X chromosome inactivation in females is a response in part to DNA methylation. Cancer, immune disease, or birth defects can occur when the methylation process becomes chronically disrupted or faulty.

DNA's bases are enzymatically methylated

In addition to cytidine methylation at carbon 5, adenine methylation is seen in bacteria, mammals, and plants. A methyl (CH₃) group is added enzymatically to yield N6-methyladenine, 5-methyl cytosine, or N4-Methyl cytosine. The level of methylation in DNA varies among species from 75% of all methylation targets to almost none for 5MC. In mammals, 5MC in CG sequences have the cytosine on both strands methylated. There are other sequence targets for 5MC in embryonic stem cells, neural development, and hematopoietic (blood-making) progenitor cells. However, there is no known purpose for the alternate targets of DNA methyltransferase, enzymes responsible for methylation of bare DNA.

Deamination of 5-methyl cytosine

The structure of 5MC is similar to that of thymine. Through a common phenomenon, 5MC goes through deamination that produces thymine. With thymine in place to pair with guanosine, a mismatch in base pairing is detected, and the mismatch repair system is activated. This system repairs the mismatched base pair to either C:G or to T:A. The second possibility represents a mutation, while the first does not. In the absence of methylation, the deamination of cytosine produces uracil. This error is generally repaired correctly.

Conserved function

In mammals, around 75% of CG dinucleotides are methylated in somatic cells, and DNA methylation appears as the default state. It has to be excluded explicitly from defined locations despite the high mutation rate that occurs when mismatch repair repairs the location of a 5MC.

CG islands

CG, as a dinucleotide, is about 21% less common than predicted in the mammalian genome. However, throughout the genome, there are islands with rich CG content. They are located especially in promotor regions, with 60% to 70% of mammalian promoters having one. Methylation of CG islands near promoters unambiguously linked to transcriptional repression and methylation of CG islands within the coding sequence represses transcription from alternate promoters.

Methylation of DNA itself may physically impede the binding of the transcription complex to the gene in the promotor region. Methylated DNA can be bound by proteins that recruit additional proteins to the locus. Histones and chromatin remodeling proteins form compact, inactive DNA, termed heterochromatin. This link between DNA methylation and dense chromatin structure is very important in the control of gene expression.

Repression of transposable elements

Methylated CG sequences can permanently silence transposable elements or transposons. The significance of transposable element silencing is unknown.

Highly transcribed genes

In all species where DNA methylation occurs, there is a correlation between transcriptional activity and the density of CG in the body of their genes. Internal CG dinucleotides silence alternative promoters within the gene and transposon activity. Methylation may serve to

In every cell, DNA is tagged with chemical groups (like flags) that make up the epigenetic code. These flags help the cell's machinery know when to activate or inactivate a gene. In many tumor cells the flags are incorrectly applied. These newly added methyl groups cause the cell to act erratically, causing the cell to express genes at the wrong levels or not at all. These flags can turn off key defensive genes that help protect the cell from becoming cancerous and disrupt other processes. When this event occurs, it's called CpG island methylation phenotype, or CIMP for short. (Darryl Leja/NHGRI/Science Source)

form the platform upon which histones bind chromatin and condense the DNA.

DNA methylation in health and disease

Embryonic development

Almost all methyl groups from parents' chromosomes are erased during gametogenesis and embryogenesis. Then, methylation occurs during the implantation of the embryo, which keeps most genes except housekeeping genes repressed. After implantation, methylation patterns assume cell-type and developmental stage-specific methylation patterns that endure in differentiated cells.

Aging

DNA methylation changes with aging, with methylation status used as a molecular clock with the highest level in infants. However, some genes, like the estrogen receptor and insulin-like growth factor, become hyper-methylated over time.

Brain

Animal researchers have found changes in methylation rates in the brain following learning activities. Then, methylation returns to the native state after several weeks. The memory remains, however.

Exercise

Demethylation slows following intense exercise in some genes in skeletal muscles and leads to increased methylation levels in adipose tissue. There is also preliminary evidence that more physical activity leads to greater DNA methylation in white blood cells.

B cell differentiation

B cells are hypomethylated throughout their differentiation. The largest difference in methylation rate is seen in germinal center B cells and memory B cells. Long-lived B cells also share a methylation pattern with B cell tumors.

Cancer

Widespread hypomethylation is linked to the development of several cancers. Changes in DNA methylation are seen during cancer development, with hypomethylation linked to chromosomal instability and loss. DNA hypermethylation is associated with promoters that allow transcription of oncogene suppressors. Cancer develops readily without oncogene suppressors.

DNA methyltransferases

Methylation of DNA in mammals is mainly on the C5 position of cytosine in CG dinucleotides. DNMT1 is the proposed maintenance methyltransferase responsible for copying DNA methylation patterns to the daughter strands during replication. At the same time, DNMT3a and DNMT3b are the de novo DNA methyltransferases that set up DNA methylation patterns early in development.

Differentially methylated regions (DMRs)

DMRs are regions of the genome that are methylated in a different pattern according to tissue type, cell type, age, disease state, or between individuals. These functional regions are involved in gene transcriptional regulation. Studying them may unlock secrets to cell differentiation or disease states.

Donohue syndrome

Definition

Donohue syndrome, also formerly called leprechaunism, is a genetic disorder caused by mutations in the insulin receptor gene. W. L. Donohue first described this rare syndrome in 1948.

Description

Donohue syndrome is a disorder that causes low birth weight, unusual facial features, and failure to thrive in infants. It is associated with the over-development of the pancreas, a gland located near the stomach. It is also considered to be the most insulin-resistant form of diabetes.

Donohue syndrome results from a mutation of the insulin receptor gene *INSR*, which prevents insulin in the blood from being processed. Therefore, even before birth the fetus exhibits insulin resistance and has high levels of unprocessed insulin in the blood. Insulin is one of two hormones secreted by the pancreas to control blood sugar (glucose) levels. Donohue syndrome is known as a progressive endocrine disorder because it relates to the growth and functions of the endocrine system, the collection of glands and organs that deliver hormones via the bloodstream.

Hormones are chemicals released by the body to control cellular function (metabolism) and maintain equilibrium (homeostasis). These hormones are released either by the endocrine system or by the exocrine system. The endocrine system consists of ductless glands that secrete hormones into the blood stream. These hormones then travel through the blood to the parts of the body where they are required. The exocrine system consists of ducted glands that release their hormones via ducts directly to the site where they are needed. The pancreas is both an endocrine and an exocrine gland. As part of the endocrine system, the pancreas acts as the original producer of estrogen and other sex hormones in fetuses of both sexes. It also regulates blood sugar through its production of the hormones insulin and glucagon. The pancreas releases insulin in response to high levels of glucose in the blood. Glucagon is released when glucose

levels in the blood are low. These two hormones act in direct opposition to each other (antagonistically) to maintain proper blood sugar levels. As an exocrine gland, the pancreas secretes digestive enzymes directly into the small intestine.

In an attempt to compensate for the high blood insulin level, the pancreas overproduces glucagon as well as the female hormone estrogen and other related (estrogenic) hormones. As excess estrogen and related hormones are produced, they affect the development of the external and internal sex organs (genitalia) of the growing baby.

Insulin mediates the baby's growth in the womb through the addition of muscle and fat. A genetic link between fetal insulin resistance and low birth weight has been suggested. Without the proper processing of insulin, the fetus will not gain weight as fast as expected. Therefore, the effects of Donohue syndrome tend to become visible during the seventh month of development, when the fetus either stops growing entirely or shows a noticeable slowdown in size and weight gain. This lack of growth is further evident at birth in affected infants, who demonstrate extreme thinness (emaciation), difficulty in gaining weight, a failure to thrive, and delayed maturation of the skeletal structure.

Genetic profile

Donohue syndrome is a non-sex-linked (autosomal) recessive disorder. In 1988, Donohue syndrome was identified as the first insulin receptor gene mutation directly related to a human disease. The gene responsible for the appearance of Donohue syndrome is the insulin receptor gene *INSR*, located on the short arm of chromosome 19 at 19p13.2. More than 40 distinct mutations of this gene have been identified. Besides Donohue syndrome, other types of non-insulin-dependent (type 2) diabetes mellitus (NIDDM) can result from mutations of this gene, including Rabson-Mendenhall syndrome and type A insulin resistance syndrome. Donohue syndrome is considered the most severe of these three *INSR*-related disorders, with Rabson-Mendenhall syndrome intermediate in severity (patients survive into their late teens or early 20s) and type A insulin resistance syndrome the mildest (it is not usually life-threatening).

Demographics

Donohue syndrome occurs in approximately one out of every four million live births. About 70 cases worldwide have been reported between 1948 and 2021, with two-thirds of reported patients being females; thus, the female: male ratio for this syndrome is 2:1. As in all recessive genetic disorders, both parents must carry the

genetic mutation in order for their child to have the disorder. Therefore, Donohue syndrome has been observed most often in cases in which the parents are related by blood (consanguineous). Parents with one child affected by Donohue syndrome have a 25% likelihood that their next child will also be affected with the disease.

Donohue syndrome appears most frequently in countries where first-cousin marriage is legally permitted. Affected families have been identified among African Americans, among First Nations tribes in Canada, in Yemen, in Israel, in Japan, in Turkey, in France, in China, and in eastern Europe. It appears, however, that the disorder can affect patients in any race or ethnic group.

Signs and symptoms

Infants born with Donohue syndrome have characteristic facial features that have been said to exhibit elfin or leprechaun-like qualities, such as a smallish head with large, poorly developed, and low-set ears; a flat nasal ridge with flared nostrils; thick lips; a greatly exaggerated mouth width; and widely spaced eyes (hypertelorism). They will be very thin and have low blood sugar (hypoglycemia) due to their inability to gain nutrition through insulin processing. They will exhibit delayed bone growth and maturation, and difficulty in gaining weight and developing (failure to thrive).

Donohue syndrome patients are prone to persistent and recurrent infections. Delayed bone growth not only leads to skeletal abnormalities but also to a compromised immune system. Many of the chemicals used by the body to fight infection are produced in the marrow of the bones. When bone maturation is delayed, these chemicals are not produced in sufficient quantities to fight off or prevent infection.

At birth, affected individuals can also have an enlarged chest, with possible breast development, excessive hairiness (hirsutism), as well as overdeveloped external sex organs because of increased estrogen production caused by an overactive pancreas. As an additional side effect of the increased sex hormones released in Donohue syndrome, these individuals often have extremely large hands and feet relative to their non-affected peer group. As the result of a lack of insulin, the infant is likely to have a relatively small amount of muscle mass, very little fat, and a distended abdomen (due to malnutrition). Additional symptoms of Donohue syndrome include pachyderma, or elephant skin, in which there is excess skin production causing large, loose folds; and abnormal coloration (pigmentation) of the skin in the folds of the body known as acanthosis nigricans. These individuals are also quite susceptible to both umbilical and inguinal hernias.

KEY TERMS

Acanthosis nigricans—A skin condition distinguished by velvety, dark patches where the skin is folded or creased.

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Chorionic villus sampling (CVS)—A procedure involving removal of a small placental sample during pregnancy to obtain fetal chromosome results.

Consanguineous—Sharing a common bloodline or ancestor.

Endocrine system—A system of ductless glands that regulate and secrete hormones directly into the bloodstream.

Fibroblasts—Cells that form connective tissue fibers like skin.

Hirsutism—The presence of coarse hair on the face, chest, upper back, or abdomen in a female as a result of excessive androgen production.

Histologic—Pertaining to histology, the study of cells and tissues at the microscopic level.

Hypoglycemia—An abnormally low glucose (blood sugar) concentration in the blood.

Insulin—A hormone produced by the pancreas that is secreted into the bloodstream and regulates blood sugar levels.

Insulin receptor gene—The gene responsible for the production of insulin receptor sites on cell surfaces. Without properly functioning insulin receptor sites, cells cannot attach insulin from the blood for cellular use.

Insulin resistance—An inability to respond normally to insulin in the bloodstream.

Insulin-like growth factor I—A hormone released by the liver in response to high levels of growth hormone in the blood. This growth factor is very similar to insulin in chemical composition, and like insulin, it is able to bring about cell growth by causing cells to undergo mitosis (cell division).

Pachyderma—An abnormal skin condition in which excess skin is produced that appears similar to that of an elephant (pachyderm).

Pancreas—An organ located in the abdomen that secretes pancreatic juices for digestion and hormones for maintaining blood sugar levels.

Serological—Pertaining to serology, the science of testing blood to detect the absence or presence of antibodies (an immune response) to a particular antigen (foreign substance).

In addition to the defect in the insulin receptor gene, Donohue syndrome is associated with problems in the epidermal growth factor receptor, which controls growth of the skin. Abnormal functioning of the epidermal growth factor receptor has been identified in three unrelated individuals affected with Donohue syndrome. This finding suggests that the probable cause of Donohue syndrome is more than just the insulin receptor. These observations may help explain the physical symptom of pachyderma in those affected with Donohue syndrome. It has also been suggested that the high concentrations of insulin close to the cell membranes lead to a lowering of growth hormone receptor activity at these locations. This lowered growth hormone activity in turn causes slowed cellular growth, which leads to systemic growth failure in affected patients.

Diagnosis

In families with a history of the disease, diagnosis in utero before birth of the fetus is possible through molecular DNA analysis of tissue samples from the chorionic

villi, which are cells found in the placenta. Molecular genetics testing for Donohue syndrome is widely available in the United States and Europe for carrier parents as well as patients.

After birth, the diagnosis of Donohue syndrome is usually made based on the blood tests that show severe insulin resistance coupled with hypoglycemia. The presence of several of the physical symptoms in addition to positive results in a test for severe insulin resistance, such as an insulin receptor defect test or a fasting hypoglycemia test, is usually sufficient for a diagnosis of Donohue syndrome. The diagnosis of Donohue syndrome may be confirmed by observed cellular (histologic) changes in the ovaries, pancreas, and breast that are not normal for the age of the patient.

Treatment and management

Genetic counseling of parents with a Donohue syndrome-affected child may help prevent the conception of additional children affected with this genetic disorder. After birth, affected infants may require treatment

for malnutrition as well as insulin-resistant diabetes. Patients with a demonstrated residual insulin receptor function may survive past infancy. In these cases, the treatment regimen must certainly include ongoing insulin-resistant diabetes care and dietetic counseling to assist with weight gain. It may also be necessary to administer growth hormone therapy to certain patients to spur growth, but this is indicated only in those individuals who show signs of functioning growth hormone receptors and no signs of higher-than-normal resistance to growth hormone.

The revolutionary impact of recombinant DNA technology, whereby scientists can mass-produce genetic material for use in medicine, has made possible another treatment method that involves the introduction of recombinant human insulin-like growth factor 1 (rhIGF-1) into the body. A case study has been reported of a female affected with Donohue syndrome and low levels of insulin-like growth factor 1 (IGF-1), which is indicative of a higher-than-normal resistance to growth hormone.

Examination of the patient's fibroblasts showed normal binding of IGF-1 and normal functioning of these fibroblasts in response to IGF-1. Fibroblasts are connective tissue cells that accomplish growth in humans by differentiating into chondroblasts, collagenoblasts, and osteoblasts, all of which are the precursor cells necessary to produce bone growth in humans. This case report indicates that if enough IGF-1 could get to the fibroblasts in the patient's body, there is every reason to believe that these fibroblasts would function normally and mature into the precursor cells needed for bone growth. This finding made the patient an ideal candidate for rhIGF-1 treatments.

In this study, the long- and short-term effects on growth patterns and glucose metabolism in the patient were studied after the treatment with rhIGF-1. The rhIGF-1 that was not immediately utilized by the patient was rapidly destroyed in the cellular conditions produced by Donohue syndrome. Therefore, to maintain the desired levels of rhIGF-1 in the blood, the patient received rhIGF-1 both in injections prior to every meal and via a continuous subcutaneous infusion method similar to that used to continuously pump insulin for some patients with diabetes. Recombinant human IGF-1 was administered to this patient over a period of six years with an observation of normal blood glucose levels and a return to normal growth patterns. Moreover, the treatment did not cause negative side effects. The results of this case study offer a promising treatment for certain individuals affected with Donohue syndrome.

A 2013 report from a group of Japanese researchers indicated that treatment with rhIGF-1 was effective for

about two years in treating a male patient with Donohue syndrome but was unsuccessful in bringing about his longer-term survival. Another case study was published in 2014 of a female treated with rhIGF-1 administered through an insulin pump. The patient's progress was interrupted, however, by the development of an ovarian tumor. The authors of the study concluded that further experience with the use of an insulin pump is needed to confirm the efficacy of continuous rhIGF-1 infusion as a treatment for Donohue syndrome.

Prognosis

Individuals born with Donohue syndrome generally die in infancy from either malnutrition or recurrent and persistent infection. All individuals affected with Donohue syndrome who survive past infancy have severe intellectual disability and profound motor skill impairment. Survival into childhood is thought to be due to some remaining insulin receptor function and the ability of extremely high insulin concentrations to transmit signals through alternate pathways.

There is an additional possibility that the mutations responsible for Donohue syndrome may increase the risk of cancer in long-term survivors. The case study of the female patient who developed ovarian cancer has already been mentioned. Another case was reported in 2013 of a female patient with Donohue syndrome who survived until age 24 with rhIGF-1 therapy but then developed cancer of the endometrium (the tissue that lines the uterus). Further research will be needed to determine whether mutations in the *INSR* gene are associated with cancer as well as insulin resistance syndromes.

Down syndrome

Definition

Down syndrome is the most common chromosome disorder and genetic cause of intellectual disability. It occurs because of the presence of an extra copy of chromosome 21. For this reason, it is also called trisomy 21.

Description

When a baby is conceived, the sperm cell from the father and the egg cell from the mother undergo a reduction of the total number of chromosomes from 46 to 23. Occasionally an error occurs in this reduction process, and instead of passing on 23 chromosomes to the baby, a parent will pass on 24 chromosomes. This event is called nondisjunction, and it occurs in 95% of Down syndrome cases. The baby therefore receives an extra

Young girl with Down syndrome. (Design Pics/Disability Images)

chromosome at conception. In Down syndrome, that extra chromosome is chromosome 21. Because of this extra chromosome 21, individuals affected with Down syndrome have 47 instead of 46 chromosomes.

Genetic profile

In approximately 1%–2% of Down syndrome cases, the original egg and sperm cells contain the correct number of chromosomes, 23 each. The problem occurs sometime shortly after fertilization—during the phase when cells are dividing rapidly. One cell divides abnormally, creating a line of cells with an extra copy of chromosome 21. This form of genetic disorder is called mosaicism. The individual with this type of Down syndrome has two types of cells: those with 46 chromosomes (the normal number), and those with 47 chromosomes (as occurs in Down syndrome). Individuals affected with this mosaic form of Down syndrome generally have less severe signs and symptoms of the disorder.

Another relatively rare genetic accident that causes Down syndrome is called translocation. During cell division, chromosome 21 somehow breaks. The broken-off piece of this chromosome then becomes attached to another chromosome. Each cell still has 46 chromosomes, but the extra piece of chromosome 21 results in the signs and symptoms of Down syndrome. Translocations occur in about 3%–4% of cases of Down syndrome.

Once a couple has had one baby with Down syndrome, they are often concerned about the likelihood of future offspring also being born with the disorder. Mothers under the age of 35 with one Down syndrome-affected child have a 1% chance that a second child will also be born with Down syndrome. In mothers 35 and older, the chance of a second child being affected with Down syndrome is approximately the same as for any woman at a similar age. However, when the baby with Down syndrome has the type that results from a translocation, it is possible that one of the two parents is a carrier of a balanced translocation. A carrier has rearranged chromosomal information and can pass it on, but he or she does not have an extra chromosome and therefore is not affected with the disorder. When one parent is a carrier of a translocation, the chance of future offspring having

Down syndrome is greatly increased. The specific risk will have to be assessed by a genetic counselor.

Demographics

Down syndrome occurs in about 1 in every 800 live births. It affects an equal number of male and female babies. The majority of cases of Down syndrome occur due to an extra chromosome 21 within the egg cell supplied by the mother (nondisjunction). As a woman's age (maternal age) increases, the risk of having a Down syndrome baby increases significantly. By the time the woman is age 35, the risk increases to 1 in 400; by age 40 the risk increases to 1 in 110; and by age 45 the risk becomes 1 in 35. There is no increased risk of either mosaicism or translocation with increased maternal age.

Down syndrome occurs with equal frequency across all ethnic groups and subpopulations.

Signs and symptoms

While Down syndrome is a chromosomal disorder, a baby is usually identified at birth through observation of a set of common physical characteristics. Not all affected babies will exhibit all of the symptoms discussed. There

Down syndrome: pedigree analysis chart (Gale)

is a large variability in the number and severity of these characteristics from one affected individual to the next. Babies with Down syndrome tend to be overly quiet, less responsive to stimuli, and have weak, floppy muscles. A number of physical signs may also be present. These include: a flat-appearing face; a small head; a flat bridge of the nose; a smaller than normal, low-set nose; small mouth, which causes the tongue to stick out and to appear overly large; upward slanting eyes; bright speckles on the iris of the eye (Brushfield spots); extra folds of skin located at the inside corner of each eye near the nose (epicanthal folds); rounded cheeks; small, misshapen ears; small, wide hands; an unusual deep crease across the center of the palm (simian crease); an inwardly curved little finger; a wide space between the great and the second toes; unusual creases on the soles of the feet; overly flexible joints (sometimes referred to as being double-jointed); and shorter-than-normal stature.

Other types of defects often accompany Down syndrome. Approximately 30%–50% of all children with Down syndrome are found to have heart defects. A number of different heart defects are common in Down syndrome. All of these result in abnormal patterns of blood flow within the heart. Abnormal blood flow within the

heart often means that less oxygen is sent into circulation throughout the body, which can cause fatigue, a lack of energy, and poor muscle tone.

Malformations of the gastrointestinal tract are present in about 5%–7% of children with Down syndrome. The most common malformation is a narrowed, obstructed duodenum (the part of the small intestine into which the stomach empties). This disorder, called duodenal atresia, interferes with the baby's milk or formula leaving the stomach and entering the intestine for digestion. The baby often vomits forcibly after feeding and cannot gain weight appropriately until the defect is repaired.

Another malformation of the gastrointestinal tract that is seen in patients with Down syndrome is an abnormal connection between the windpipe (trachea) and the digestive tube of the throat (esophagus) called a tracheoesophageal fistula (T-E fistula). This connection interferes with eating and/or breathing because it allows air to enter the digestive system and/or food to enter the airway.

Other medical conditions occurring in patients with Down syndrome include an increased chance of developing infections, especially ear infections and pneumonia; certain kidney disorders; thyroid disease (especially low

or hypothyroid); hearing loss; vision impairment requiring glasses (corrective lenses); and a 20 times greater chance than the population as a whole of developing leukemia.

Development in a baby and child affected with Down syndrome occurs at a much slower than normal rate. Because of weak, floppy muscles (hypotonia), babies learn to sit up, crawl, and walk much later than their unaffected peers. Talking is also quite delayed. The level of intellectual disability is considered to be mild-to-moderate in Down syndrome. The degree of intellectual disability varies a great deal from one child to the next. While it is impossible to predict the severity of Down syndrome at birth, with proper education, children who have Down syndrome are capable of learning. Most children affected with Down syndrome can read and write and are placed in special education classes in school. The majority of individuals with Down syndrome become semi-independent adults, meaning that they can take care of their own needs with some assistance.

As people with Down syndrome age, they face an increased chance of developing the brain disease called Alzheimer's (sometimes referred to as dementia or senility). Most people have a 12% chance of developing Alzheimer's, but almost all people with Down syndrome will have either Alzheimer disease or a similar type of dementia by the age of 50. Alzheimer disease causes the brain to shrink and to break down. The number of brain cells decreases, and abnormal deposits and structural arrangements occur. This process results in a loss of brain functioning. People with Alzheimer's have strikingly faulty memories. Over time, people with Alzheimer's disease will lapse into an increasingly unresponsive state.

As people with Down syndrome age, they also have an increased chance of developing a number of other illnesses, including cataracts, thyroid problems, diabetes, and seizure disorders.

Diagnosis

Diagnosis is usually suspected at birth, when the characteristic physical signs of Down syndrome are noted. Once this suspicion has been raised, genetic testing (chromosome analysis) can be undertaken in order to verify the presence of the disorder. This testing is usually done on a blood sample, although chromosome analysis can also be done on other types of tissue, including the skin. The cells to be studied are prepared in a laboratory. Chemical stain is added to make the characteristics of the cells and the chromosomes stand out. Chemicals are added to prompt the cells to go through normal development up to the point where the chromosomes are most visible, prior to cell division. At this point, they are

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Intellectual disability—Significant impairment in intellectual function and adaptation in society. Usually associated with an intelligence quotient (IQ) below 70.

Karyotype—A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order from largest to smallest.

Mosaic—A term referring to a genetic situation in which an individual's cells do not have the exact same composition of chromosomes. In Down syndrome, this may mean that some of the individual's cells have a normal 46 chromosomes, while other cells have an abnormal 47 chromosomes.

Nondisjunction—Nonseparation of a chromosome pair, during either meiosis or mitosis.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosome material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Trisomy—The condition of having three identical chromosomes instead of the normal two in a cell.

examined under a microscope and photographed. The photograph is used to sort the different sizes and shapes of chromosomes into pairs. In most cases of Down syndrome, one extra chromosome 21 will be revealed. The final result of such testing, with the photographed chromosomes paired and organized by shape and size, is called the individual's karyotype. An individual with Down syndrome will have a 47 XX+21 karyotype if they are female and a 47 XY+21 karyotype if they are male.

Women who become pregnant after the age of 35 are offered prenatal tests to determine whether their developing baby is affected with Down syndrome. A genetic counselor meets with these families to inform them of the risks and to discuss the types of tests available

to make a diagnosis prior to delivery. Because there is a slight risk of miscarriage following some prenatal tests, all testing is optional, and couples need to decide whether they desire to take this risk in order to learn the status of their unborn baby.

Screening tests are used to estimate the chance that an individual woman will have a baby with Down syndrome. A test called the maternal serum alpha-fetoprotein test (MSAFP) is offered to all pregnant women under the age of 35. If the mother decides to have this test, it is performed between 15 and 22 weeks of pregnancy. The MSAFP screen measures a protein and two hormones that are normally found in maternal blood during pregnancy. A specific pattern of these hormones and protein can indicate an increased risk for having a baby born with Down syndrome. However, this is only a risk and MSAFP cannot diagnose Down syndrome directly. Women found to have an increased risk of their babies being affected with Down syndrome are offered amniocentesis. The MSAFP test can detect up to 60% of all babies who will be born with Down syndrome.

Ultrasound screening for Down syndrome is also available. This is generally performed in the mid-trimester of pregnancy. Abnormal growth patterns characteristic of Down syndrome such as growth retardation, heart defects, duodenal atresia, T-E fistula, shorter than normal long-bone lengths, and extra folds of skin along the back of the neck of the developing fetus may all be observed via ultrasonic imaging.

The only way to definitively establish (with about 99% accuracy) the presence or absence of Down syndrome in a developing baby is to test tissue during the pregnancy itself. This is usually done either by amniocentesis or chorionic villus sampling (CVS). All women under the age of 35 who show a high risk for having a baby affected with Down syndrome via an MSAFP screen and all mothers over the age of 35 are offered either CVS or amniocentesis. In CVS, a tiny tube is inserted into the opening of the uterus to retrieve a small sample of the placenta (the organ that attaches the growing baby to the mother via the umbilical cord and provides oxygen and nutrition). In amniocentesis, a small amount of the fluid in which the baby is floating is withdrawn with a long, thin needle. CVS may be performed as early as 10 to 12 weeks into a pregnancy. Amniocentesis is generally not performed until at least the 15th week. Both CVS and amniocentesis carry small risks of miscarriage. Approximately 1% of women miscarry after undergoing CVS testing, while approximately one-half of 1% miscarry after undergoing amniocentesis. Both amniocentesis and CVS allow the baby's own karyotype to be determined.

QUESTIONS TO ASK YOUR DOCTOR

- What does the term "trisomy 21" mean when speaking about Down syndrome?
- What caused my child to be born with Down syndrome?
- What is the extent of intellectual disability that my child has experienced as a result of her Down syndrome?
- Are there medical problems we should expect to see in the future as the result of our child's Down syndrome?

Approximately 75% of all babies diagnosed prenatally as affected with Down syndrome do not survive to term and spontaneously miscarry. In addition, these prenatal tests can only diagnose Down syndrome, not the severity of the symptoms that the unborn child will experience. For this reason, a couple might use this information to begin to prepare for the arrival of a baby with Down syndrome, to terminate the pregnancy, or in the case of miscarriage or termination, decide whether to consider adoption as an alternative.

Treatment and management

No treatment is available to cure Down syndrome. Treatment is directed at addressing the individual concerns of a particular patient. For example, heart defects may require surgical repair, as will duodenal atresia and T-E fistula. Many Down syndrome patients will need to wear glasses to correct vision. Patients with hearing impairment benefit from hearing aids.

While some decades ago all children with Down syndrome were quickly placed into institutions for life-long care, research shows very clearly that the best outlook for children with Down syndrome is a normal family life in their own home. This requires careful support and education of the parents and the siblings. It is a life-changing event to learn that a new baby has a permanent condition that will affect essentially all aspects of his or her development. Some community groups help families deal with the emotional effects of raising a child with Down syndrome. Schools are required to provide services to children with Down syndrome, sometimes in separate special education classrooms, and sometimes in regular classrooms (this is called mainstreaming or inclusion).

Prognosis

The prognosis for an individual with Down syndrome is quite variable, depending on the types of complications (heart defects, susceptibility to infections, development of leukemia, etc.). The severity of the retardation can also vary significantly. Without the presence of heart defects, about 90% of children with Down syndrome live into their teens. People with Down syndrome appear to go through the normal physical changes of aging more rapidly, however. The average age of death for an individual with Down syndrome is about 50 to 55 years.

Still, the prognosis for a baby born with Down syndrome is better than ever before. Because of modern medical treatments, including antibiotics to treat infections and surgery to treat heart defects and duodenal atresia, life expectancy has greatly increased. Community and family support allows people with Down syndrome to have rich, meaningful relationships. Because of educational programs, some people with Down syndrome are able to hold jobs.

Approximately 60% of women with Down syndrome are fully capable of having children. The risk of a woman with trisomy 21 having a child affected with Down syndrome is 50%.

Duane syndrome

Definition

Duane syndrome (DS), also called Duane retraction syndrome (DRS), is a congenital disorder that limits the movement of the eye. It may also involve other systems of the body.

Description

Duane syndrome is an inherited disorder characterized by a limited ability to move the eye to one side or the other. DS is congenital, meaning that it is present at birth. It results from abnormal connections among the nerves that control the muscles of the eyes. About 80% of DS cases involve one eye (unilateral), and about 20% involve both eyes (bilateral). Most unilateral DS cases (72%) involve the left eye.

DS was first described in 1905 by American ophthalmologist Alexander Duane (1858–1926). It also is known as:

- Duane retraction syndrome (DUS)
- DR syndrome
- eye retraction syndrome
- retraction syndrome
- Stilling-Turk-Duane syndrome

DS is one of a group of conditions known as strabismus, or misalignment of the eye. It is classified as an incomitant strabismus because it is a misalignment of the eye that varies, depending on the direction that the eye is gazing. It is further classified as an extraocular muscle fibrosis syndrome, which means that it is a condition associated with the muscles that move the eyes. Both the active and the passive movement of the eyeball are affected in DS.

Physiology

DS is believed to result from an abnormality that occurs during the development of the fetus in the womb. It may be caused by either environmental factors, genetic factors, or a combination of both. The developmental abnormality is believed to occur between the third and eighth weeks of fetal development. This is the period when the ocular muscles that rotate the eye and the cranial nerves from the brain that control the ocular muscles are forming in the fetus.

DS appears to result from the absence of cranial nerve VI, which is known as the abducens nerve. The nerve cells in the brain that connect to the abducens nerve are also missing. The abducens nerve controls the lateral rectus muscle of the eye. This muscle moves one eye outward toward the ear as a person looks toward that side. This movement is called abduction. In DS, the nerves from a branch of cranial nerve III (the oculomotor nerve) also are abnormal. The oculomotor nerve controls several eye muscles, including the medial rectus muscle. This muscle moves the eye inward toward the nose as the person looks toward the other side. This movement is called adduction.

The majority of individuals with DS have limited or no ability to move an eye outward toward the ear. Instead, the opening between the eyelids (palpebral fissure) of that eye widens, and the eyeball protrudes. In addition, individuals with DS may have only a limited ability to move

the eye inward toward the nose. Instead, when looking inward toward the nose, the medial and lateral recti muscles contract simultaneously. This causes the eyeball to retract, or pull into the skull; and it causes the opening between the eyelids to narrow as if one were squinting. Sometimes, the eye moves up or down as the individual attempts to look toward the nose. This is called upshoot or downshoot, respectively.

In some individuals with DS, the eyes may cross when looking straight ahead. Gazing straight ahead is called the primary position or primary gaze. Crossed eyes may cause the person to turn the head to one side or the other to restore binocular vision. In such individuals, this head turning may become habitual.

Associated syndromes

About 30% to 50% of individuals with DS have associated abnormalities. These may include additional eye problems, deafness, or nervous system or skeletal abnormalities. In particular, DS may be associated with abnormalities in the upper extremities, especially the hands. Sometimes DS is associated with Holt-Oram syndrome, a hereditary heart defect.

Okihiro syndrome is DS in association with other abnormalities that may include:

- flatness in the normally fleshy region between the thumb and the wrist (the thenar eminence) of one or both hands

- inability to flex the joint in the thumb
- hearing loss or deafness in one or both ears

Okiihiro syndrome also is known as:

- Duane syndrome with radial ray anomalies (as in the arms and hands)
- Duane/radial dysplasia syndrome (referring to abnormal tissue growth in the arms and hands)
- DR syndrome (the “D” refers to Duane anomaly and deafness; the “R” refers to radial and renal [kidney] dysplasia, or abnormal tissue growth in the arms, hands, and kidneys)
- Duane anomaly with radial ray abnormalities and deafness

Genetic profile

Portions of several of the 23 pairs of human chromosomes may be associated with DS. A gene that is involved in DS has been localized to a region of chromosome 2. Deletions of portions of chromosomes 4 and 8 have also been associated with DS. The presence of an additional small chromosome, thought to be broken off from chromosome 22, has been associated with DS. It is possible that these chromosome rearrangements and abnormalities may account for the wide range of symptoms and syndromes that can occur with DS. Three genes firmly associated with for DS and the associated syndromes have been identified. These are *CHN1*, *MAFB*, and *SALL4*. It is possible that DS arises from a combination of environmental factors and defects in one or more of these genes.

About 90% of cases of DS arise spontaneously. Among the other 10% that are familial, the inheritance of DS is autosomal, meaning that the trait is not carried on either the X or Y sex chromosomes. The most common type of DS, DS1, is inherited as an autosomal dominant trait. This means that only a single copy of a DS gene, inherited from one parent, can result in the condition. The offspring of a parent with DS is expected to have a 50% chance of inheriting the disorder. Some forms of DS are inherited in a recessive pattern. This requires the individual to inherit two copies of a gene, one from each parent.

Family members may exhibit different types of DS, indicating that the same genetic defect may be expressed by a range of symptoms. The severity of DS also may vary among family members. Furthermore, the majority of individuals with DS do not appear to have a family history of the disorder. There are very few reports of single families with a large number of affected individuals. However, close relatives of individuals with DS often

KEY TERMS

Abducens nerve—Cranial nerve VI; the nerve that extends from the midbrain to the lateral rectus muscle of the eye and controls movement of the eye toward the ear (abduction).

Abduction—Turning away from the midline of the body.

Adduction—Movement toward the midline of the body. In Duane retraction syndrome, turning the eye inward toward the nose.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Congenital—Referring to a disorder that is present at birth.

Downshoot—Downward movement of the eye.

Dysplasia—The abnormal growth or development of a tissue or organ.

Extraocular muscle fibrosis—Abnormalities in the muscles that control eye movement.

Head turn—Habitual head position that has been adopted to compensate for abnormal eye movements.

Holt-Oram syndrome—An inherited disorder characterized by congenital heart defects and abnormalities of the arms and hands; may be associated with Duane retraction syndrome.

Lateral rectus muscle—The muscle that turns the eye outward toward the ear (abduction).

Medial rectus muscle—The muscle that turns the eye inward toward the nose (adduction).

Oculomotor nerve—Cranial nerve III; the nerve that extends from the midbrain to several of the muscles that control eye movement.

Okiihiro syndrome—An inherited disorder characterized by abnormalities of the hands and arms and hearing loss; may be associated with Duane retraction syndrome.

Primary position, primary gaze—When both eyes are looking straight ahead.

Recessive—Referring to a genetic trait expressed only when present on both members of a pair of chromosomes, one inherited from each parent.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

Upshoot—Upward movement of the eye.

are affected by some of the other abnormalities that may be associated with the disorder.

Okihiro syndrome, or Duane syndrome with radial ray anomalies, and Holt-Oram syndrome are both inherited as autosomal dominant traits. However, Okihiro syndrome may skip a generation in a family or may be expressed by a range of symptoms within one family.

Demographics

DS is estimated to affect 0.1% of the general population. It accounts for 1% to 5% of all eye-movement disorders. Although it is not a sex-linked disorder, females are more likely than males to be affected by DS (60%, compared with 40%).

Signs and symptoms

Types of DS

There are three generally recognized types of DS. Type 1 DS (DS1) accounts for about 70% of cases. With DS1, abduction, the ability to move the eye toward the ear, is limited or absent. The palpebral fissure (the opening between the eyelids) widens, and the eyeball protrudes when the eye is moved outward. In contrast, adduction, the ability to move the eye toward the nose, is normal or almost normal. However, the palpebral fissure narrows and the eyeball retracts during adduction. The eyes of infants and children with DS1 are usually straight ahead in the primary position. However, some children develop an increasing misalignment in the primary position and may compensate by turning their head.

With DS type 2, adduction is limited or absent, but abduction is normal or only slightly limited. The palpebral fissure narrows, and the eyeball retracts during adduction. Type 2 accounts for approximately 7% of DS cases.

With DS type 3, both abduction and adduction are limited. The palpebral fissure narrows, and the eyeball retracts during adduction. Type 3 accounts for about 15% of DS cases.

Each type of DS is subclassified according to the symptoms that occur when the individual is looking straight ahead (primary gaze). With subgroup A, the eye turns in toward the nose when gazing ahead. With subgroup B, the eye turns out toward the ear during a primary gaze. With subgroup C, the eyes are straight ahead in the primary position.

Associated symptoms

Although many individuals with DS are healthy and have no other symptoms, other body systems that may be affected with DS include:

QUESTIONS TO ASK YOUR DOCTOR

- What is the connection between my child's Duane retraction syndrome and strabismus?
- What caused my child's DS?
- Are there surgical procedures to treat Duane syndrome?
- If my child has been diagnosed with Duane retraction syndrome, what are the chances that future children will be born with the same condition?

- skeleton
- ears and hearing
- additional involvement of the eyes
- nervous system

With Okihiro syndrome, DS can be unilateral or bilateral. In addition to a flatness at the base of the thumb, there may be difficulty with thumb movements. There also may be abnormalities or the complete absence of the radial and ulnar bones of the forearm. In extreme cases, the thumb or forearm may be absent. Okihiro syndrome may be accompanied by hearing loss; abnormal facial appearance; and heart, kidney, and spinal abnormalities.

Sometimes, Wildervanck syndrome is associated with DS; this syndrome may include congenital deafness and a fusion of the cervical (neck) vertebrae (C2 and C3).

Diagnosis

Most children with DS are diagnosed by age 10. The clinical evaluation includes a complete family history, an eye examination, and examinations for other eye involvement or other physical abnormalities.

Eye examinations include the following measurements:

- visual acuity or sharpness
- alignment of the eyes
- range of motion of the eyes
- retraction (pulling in) of the eyeballs
- size of the eye opening between the eyelids
- upshoots and downshoots
- head turns

Hearing tests are frequently conducted. The cervical (neck) and thoracic (chest) parts of the spine, the

vertebrae, the hands, and the roof of the mouth all are included in the examination as well.

Treatment and management

Special glasses with prisms can eliminate the head turning that is associated with DS. Vision therapy may help with secondary vision problems.

Surgery may be performed for the following cosmetic reasons:

- abnormalities in the primary gaze (when looking straight ahead)
- an unusual compensatory head position
- a large upshoot or downshoot
- severe retraction of the eye

The goal of surgery is to reduce or eliminate the misalignment of the eye that causes abnormal head turning, as well as to reduce the retraction of the eyeball and the upshoots and downshoots. The surgery is directed at the affected muscles of the eye.

Children with DS, as well as their siblings, require complete medical examinations to detect other abnormalities that may be associated with DS.

Prognosis

If children with DS go undiagnosed, a permanent loss of vision may occur. Surgical procedures may eliminate head turns and improve the misalignment of the eyes, particularly in the primary position. However, the absence of nerves for controlling the muscles of the eye cannot be corrected, and the prognosis for surgery is mediocre. Thus, no surgical procedure can completely eliminate the abnormal eye movements, and children with some binocular vision may do better without surgery. The condition does not worsen during the course of one's life.

Dubowitz syndrome

Definition

Dubowitz syndrome is a genetic disorder defined by slow growth, a characteristic facial appearance, and a small head.

Description

Dubowitz syndrome was first described in 1965 by English physician Victor Dubowitz. This genetic disorder causes growth retardation both before and after birth. It is primarily diagnosed through the distinctive facial features of affected individuals, including a small triangular-shaped face with a high forehead and wide-set, slitted eyes. A number of other symptoms, most commonly irritation and itching of the skin (eczema), may be present in infants born with Dubowitz syndrome.

Genetic profile

Dubowitz syndrome is passed on through an autosomal recessive pattern of inheritance. "Autosomal" means that the syndrome is not carried on a sex chromosome, while "recessive" means that both parents must carry the gene mutation in order for their child to have the disorder. Parents with one child affected by Dubowitz syndrome have a 25% chance that their next child will also be affected with the disorder.

The specific gene mutation responsible for Dubowitz syndrome has not yet been identified, although some individuals diagnosed with the syndrome have mutations in the *NSUN4* and *LIG4* genes.

KEY TERMS

Eczema—Inflammation of the skin with redness and other variable signs such as crusts, watery discharge, and itching.

Microcephaly—An abnormally small head.

Ptosis—Drooping of the upper eyelid.

Demographics

Cases of Dubowitz syndrome have been reported from many different regions of the world, with the majority coming from the United States, Germany, and Russia. There does not appear to be any clear-cut ethnic pattern to the incidence of the syndrome. Dubowitz syndrome appears to affect males and females with equal probability. The overall incidence of the disorder has not been established since it is very rare. As of 2021, approximately 200 cases had been reported worldwide.

Signs and symptoms

Physical characteristics

The symptoms of people diagnosed with Dubowitz syndrome vary considerably. However, the most common physical characteristics associated with Dubowitz syndrome are growth retardation, characteristic facial appearance, and a very small head (microcephaly). A wide variety of secondary physical characteristics may be present.

Growth retardation

Children born with Dubowitz syndrome usually have a low birth weight. Slower than normal growth continues after birth. Even if the infant is born in the normal range, the height and weight gradually falls toward the low end of growth curves during childhood. However, Dubowitz syndrome is not a form of dwarfism because affected individuals have normally proportioned bodies.

Facial appearance

The characteristic facial appearance of people with Dubowitz syndrome is the primary way in which the disorder is recognized. The face is small and often triangular in shape with a pointed, receding chin. The nose is broad with a wide or rounded tip. The eyes are set far apart and sometimes appear slitted due to a decreased distance between the top and bottom eyelids or a drooping top eyelid. The forehead is high, broad, and sloping.

Eyebrows and hair are thin or absent. The ears may be abnormally shaped or placed.

Microcephaly

Infants born with Dubowitz syndrome have primary microcephaly, or a small head size at birth. By definition, in microcephaly the circumference of the head is in the second percentile or less, meaning that 98% or more of all infants have a larger head circumference than an infant with microcephaly.

Other physical characteristics

There are many other physical characteristics that have been observed in the majority of cases of Dubowitz syndrome, although they are not present in all affected individuals. These include the following:

- A soft or high-pitched cry or voice
- Partial webbing of the toes
- Cleft palate or less severe palate malformations
- Genital abnormalities, including undescended testicles
- Gastroesophageal reflux
- Inflammation and itching of the skin (eczema)

Mental and behavioral characteristics

Despite the small head size of children born with Dubowitz syndrome, developmental delay is not observed in all cases. Estimates of the incidence of developmental delay in cases of Dubowitz syndrome range from 30% to 70%, and in most cases the level of the intellectual disability is rather mild.

A number of behavioral characteristics have been described by parents of children with Dubowitz syndrome, as well as in the medical literature. These include the following:

- Extreme hyperactivity
- Temper tantrums, difficulty in self-calming
- Preference for concrete thinking rather than abstract thinking
- Language difficulties
- Shyness and aversion to crowds
- Fondness for music and rhythm

Diagnosis

Since the genetic cause is not known, there is no specific medical test that can definitively assign the diagnosis of Dubowitz syndrome. The diagnosis is usually based on the characteristic facial appearance of the affected individual as well as on other factors such as growth data and medical history. The diagnosis is easily

QUESTIONS TO ASK YOUR DOCTOR

- What physical and mental features are characteristic of Dubowitz syndrome?
- By what other names is this condition known?
- What kinds of treatments, lifestyle conditions, and other factors will contribute to a positive prognosis for a child born with Dubowitz syndrome?
- How is Dubowitz syndrome diagnosed?

missed if the physician is not familiar with genetic pediatric conditions.

Treatment and management

A number of chronic medical conditions are associated with Dubowitz syndrome. These include the following:

- Inflammation and itching of the skin (eczema)
- Susceptibility to viral infections
- Allergies
- Chronic diarrhea or constipation
- Feeding difficulties and vomiting

These conditions need to be managed individually with appropriate treatments. For example, skin creams containing corticosteroid drugs are used to treat eczema.

Other physical problems caused by Dubowitz syndrome, such as drooping eyelids (ptosis) or cardiovascular defects, can be corrected through surgery.

Prognosis

The prognosis for individuals affected by Dubowitz syndrome is good, provided that management of their medical conditions is maintained. Dubowitz syndrome has not been reported to cause shortened lifespan or any degenerative conditions. People with Dubowitz syndrome can expect to survive to adulthood and lead a fairly normal lifestyle, although most have some level of intellectual disability.

Duchenne and Becker muscular dystrophy

Definition

The conditions called muscular dystrophies are characterized by muscle weakness and degeneration. Duchenne muscular dystrophy is a relatively common severe muscular dystrophy. Becker muscular dystrophy is less common and less severe. Duchenne and Becker muscular dystrophy were once considered to be separate conditions. In the 1990s, however, researchers showed that they have the same etiology (underlying cause). The two disorders nonetheless remain distinct based on their different ages of onset, rates of progression, and some distinctive symptoms. Duchenne muscular dystrophy is named for Guillaume-Amand-Duchenne de Boulogne, the French neurologist who first described it in 1861. Becker muscular dystrophy is named for Peter Emil

Becker, a German geneticist who identified the disorder in the late 1940s.

Description

Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are both defined by progressive muscle weakness and atrophy. Both conditions are caused by a mutation in the same gene and usually affect only boys. Symptoms of DMD typically begin in childhood, and boys with DMD are often confined to wheelchairs by the age of 12 years. Symptoms of BMD begin later, and men with BMD typically do not require wheelchairs until their 20s or even later.

Boys with DMD are usually diagnosed at a young age. Boys with BMD are diagnosed much later. Both conditions are progressive, although DMD progresses more quickly than BMD. Unfortunately, no treatments exist to slow or prevent progression of either disease. Skeletal muscles are affected initially. Eventually the muscles of the heart are also affected, and both conditions are fatal. The life expectancy of males with either Duchenne or Becker muscular dystrophy is 26 years and approximately 45 years, respectively. Both conditions are caused by disorders of the muscle tissue itself, not of the nerves that control the muscle.

Genetic profile

Duchenne and Becker muscular dystrophy are both caused by mutations in the *DMD* gene on the short arm of the X chromosome at Xp21.2-p21.1. This is the largest gene found in humans, and control of its expression is complex.

Humans each have 46 chromosomes, of which 23 are inherited from the mother and 23 are inherited from the father. The sets of 23 chromosomes are complementary: each contains the same set of genes. Therefore, every human has a pair of every gene. Genes are the sequences of DNA that encode instructions for growth, development, and functioning. One of the 23 pairs of chromosomes, the sex chromosomes, may not be complementary. Boys have an X chromosome and a Y chromosome; girls have two X chromosomes.

Scientists often say that every person has the same genes and that the genes on a pair of complementary chromosomes are the same. It is true that a specific gene at a specific place on each chromosome provides the body with a very specific instruction (i.e., plays a particular functional role). However, most genes have multiple forms. Scientists call the various forms of a gene *alleles*. A given gene may have multiple alleles that function normally and multiple alleles that lead to physical problems.

Mutations (changes) in the *DMD* gene cause Duchenne and Becker muscular dystrophy. The *DMD* gene provides instructions for a protein called dystrophin, a structural protein. Mutations in the *DMD* gene associated with DMD often completely disrupt production of dystrophin, such that no or very little dystrophin is present. Mutations in the *DMD* gene associated with BMD lead to a reduced amount of dystrophin being made and/or abnormal dystrophin. Certain mutations (alleles) in the *DMD* gene lead to the symptoms of DMD, while other mutations lead to the symptoms of BMD.

Sex-linked inheritance

Because the *DMD* gene is located on the X chromosome, Duchenne and Becker muscular dystrophy usually affects only boys. Most females have two X chromosomes. Therefore, if a female inherits an X chromosome with a mutation in the *DMD* gene, she has another normal *DMD* gene on her other X chromosome that protects her from developing symptoms. Women who have one mutated gene and one normal gene are called *carriers*. Boys, on the other hand, have an X and a Y chromosome. The Y chromosome has a different set of genes from the X chromosome; it mostly contains genes that provide instructions for male development. If a boy has a mutation in the *DMD* gene on his X chromosome, he has no normal *DMD* gene, and he develops symptoms of muscular dystrophy.

If a woman has one son with Duchenne or Becker and no other family history, she may or may not be a carrier. If a woman has another family member with Duchenne or Becker muscular dystrophy *and* a son with muscular dystrophy, it is assumed that she is a carrier. The risk for a male child to inherit the mutated gene from his carrier mother is 50% with each pregnancy. Based on the family history, geneticists can determine the likelihood that a woman is or is not a carrier. Based on this estimate, risks of having a son with muscular dystrophy can be provided.

New mutations

The *DMD* gene is very large, and new mutations are fairly common. A new mutation is a mutation that occurs for the first time in the affected person. Approximately one-third of males with DMD who have no family history of muscular dystrophy have the condition because of a new mutation that is present only in themselves. In this case, the affected male's mother is not a carrier. Approximately two-thirds of males with DMD and no family history have the disorder because of a new mutation that occurred in a relative. In other words, even if the affected male is the first in his family to have DMD, his mother may still be a carrier. The new mutation could have happened for the first time in the affected male's

mother, or the new mutation could have occurred in his maternal grandmother or grandfather (or their parents, or their parents, etc.).

Sometimes a man has mutations in the *DMD* gene of his sperm or a woman in her eggs but not in the other cells of his or her body. The mutation may even be in some sperm or eggs but not in others. This situation is called *germline mosaicism*. Germline cells are the precursors of eggs and sperm. A woman or man with germline mosaicism may have more than one affected son even though genetic studies of his or her blood show that he or she is not a carrier. Geneticists can estimate the risk that a person has germline mosaicism, and provide information regarding the risk for a person with germline mosaicism to have a child with muscular dystrophy.

Demographics

DMD, the most common form, affects approximately 1 in 3,500 males. Males from every ethnicity are affected. BMD is much less common than DMD. The incidence of BMD is lower, approximately 1 in 30,000 males, or between 17 and 27 cases per million. Between 400 and 600 boys are born each year in the United States with either DMD or BMD. Cases of DMD in women are extremely rare; only two have been recorded as of 2021.

Signs and symptoms

Both Becker and Duchenne muscular dystrophy initially affect skeletal muscle. Muscle weakness is the first symptom. Both conditions are progressive, but DMD progresses more rapidly than BMD. People with DMD usually begin to use a wheelchair in their early teens, while people with BMD may not use a wheelchair until their 20s or later. In the late stages of both diseases, the cardiac muscles begin to be affected. Impairment of the heart and cardiac muscles leads to death. Some female carriers have mild muscle weakness.

People with muscular dystrophy often develop contractures. A contracture makes a joint difficult to move. The joint becomes frozen in place, sometimes in a painful position. Scoliosis (curvature of the spine from side to side) is another common problem. Most people with DMD have normal intelligence, but cognition is affected in some. Cognition is not usually affected in patients diagnosed with Becker.

Dystrophin

The *DMD* gene contains instructions for a structural protein called dystrophin. Dystrophin is part of muscle cells and some nerve cells. Its function is not entirely understood. Based on its location in the muscle cell, scientists think that it may help maintain the structural

integrity of muscle cells as they contract. People with DMD make very little or no dystrophin, and people with BMD either make less than normal amounts of the protein or make only semi-functional dystrophin. When there is not enough dystrophin in muscle tissue, it becomes weak and starts to waste away (atrophy). The muscle tissue is replaced by a fatty, fibrous tissue.

Duchenne muscular dystrophy

The first symptoms of DMD are usually noticed in early childhood. Delays in developmental milestones, such as sitting and standing, are common. The affected child's gait is often a characteristic waddle or toe-walk. The child often stumbles, and running is difficult. While parents notice these symptoms retrospectively, and may notice them at the time, muscular dystrophy often is not suspected until additional signs are apparent. By the age of four to five years, it is difficult for the child to climb stairs or rise from a sitting position on the floor. It is around this time that the diagnosis is usually made. A particular sign of the disorder called Gowers' sign appears. The sign occurs when the child has to use his hands and arms to raise himself from sitting on the floor. These motor problems are caused by weakness in the large muscles close to the center of the body (proximal).

Although some muscles, such as the calves, appear to be large and defined, the muscle is actually atrophied and weak. It appears large because deposits of fatty fibrous tissue are replacing muscle tissue. Enlarged calves are a characteristic sign of DMD and are said to have pseudohypertrophy. Other muscles may also exhibit pseudohypertrophy. These muscles feel firm if massaged.

The weakness begins at the center of the body (the pelvis) and progresses outward from the hips and shoulders to the large muscles of the legs, lower trunk, and arms. The weakness is symmetrical; that is, both sides of the body are equally weak. Such early signs of weakness as stumbling and difficulty climbing progress to the point that the affected boy is unable to walk at all. Boys with DMD usually require wheelchairs by the age of 12 years. Eventually the muscles that support the neck are affected. The muscles of the digestive tract are affected in some males in the later stages of the disease. Contractures and scoliosis develop. Some boys also have learning disabilities or mild intellectual disability.

Cardiac symptoms and life expectancy

The weakness usually affects skeletal muscles first, then cardiac muscle. Skeletal muscles are those that attach to bones and produce movement. The muscle weakness of both Duchenne and Becker muscular dystrophy

progresses to affect the cardiac muscles. Weak, abnormal cardiac muscles cause breathing difficulties and a heart problem known as cardiomyopathy, which eventually leads to heart failure. Breathing difficulties lead to such lung infections as aspiration pneumonia. These problems are fatal in DMD and are often fatal in BMD. The life expectancy for a boy with DMD is the late teens or early 20s. The average life expectancy of males with Becker muscular dystrophy is the mid-40s.

Becker muscular dystrophy

The initial signs of BMD may be subtle. The age at which symptoms become apparent is later and more variable than in DMD. The progression of BMD is slower than that of DMD. Like DMD, boys with BMD develop symmetrical weakness of proximal muscles. The calf muscles often appear especially large. Boys with DMD develop weakness in the muscles that support their necks, but boys with BMD do not. The incidence and severity of learning disabilities and mild intellectual disability is less in BMD than in DMD.

The first symptoms of BMD usually appear in the 20s and may appear even later. Weakness of the quadriceps (thigh muscle) or cramping with exercise may be the first symptom. The age of onset and rate of progression are influenced by how much dystrophin is made and how well it functions. Not all males with BMD become confined to wheelchairs. If they are, the age at which they begin to use the wheelchair is later than in DMD. Many males with BMD are still ambulatory (able to walk) in their 20s. However, many males with BMD eventually develop cardiac problems, even if they do not have a great deal of skeletal muscle weakness. Cardiac problems are typically fatal by the mid-40s. Some men with BMD, however, remain ambulatory (and alive) into their 60s.

Since Duchenne and Becker muscular dystrophy are caused by a mutation (change) in the same gene, the two conditions are usually distinguished based on age of onset and rate of progression. Males with DMD usually require wheelchairs by the age of 12 years, and males with BMD usually do not require wheelchairs until after the age of 16. However, some males with muscular dystrophy develop symptoms at an intermediate age. Similarly, some males have elevated creatine kinase and abnormal muscle biopsies but do not develop most of the symptoms typical of muscular dystrophy. Some doctors would classify these males with very mild symptoms as having mild BMD. Some individuals who have BMD with mildly affected skeletal muscles still develop abnormalities of their cardiac muscle.

Many other forms of muscular dystrophy exist and are part of the diagnoses considered when a person

develops signs of Duchenne or Becker muscular dystrophy. The symptoms of BMD, in particular, may be caused by many other conditions. However, diagnostic studies can definitively confirm whether an individual has BMD.

Affected females

Although it is unusual, a few females have some or all of the symptoms of muscular dystrophy. Assuming that the diagnosis is correct, the symptoms can happen for various reasons. If a woman has Turner syndrome, in which she has one X chromosome instead of two, she could also develop Duchenne or Becker muscular dystrophy because she has no second X chromosome with a normal *DMD* gene to protect her. Alternatively, a woman may have muscular dystrophy because of random unfavorable X inactivation or because she has a chromosomal translocation. Rarely, she may also have inherited both X chromosomes from the same parent.

Diagnosis

The diagnosis of muscular dystrophy is based on physical symptoms, family history, muscle biopsy, measurement of creatine kinase, and genetic testing. Creatine kinase (CK) may also be called creatine phosphokinase or CPK. It is a protein present in skeletal muscle, cardiac muscle, and the brain.

Creatine kinase is released into the blood as muscle cells die. The level of CK in the blood is increased when a person has muscular dystrophy. The level of CK in a male with DMD is often more than ten times the normal level, and the level in a male with BMD is often at least five times more than the normal level. The level of CK in the blood of female carriers is variable. Approximately 50% of DMD carriers have slightly to greatly elevated serum creatine kinase levels. Only about 30% of carriers of BMD have elevated creatine kinase. Therefore, the measurement of creatine kinase is not an accurate predictor of carrier status.

If a muscle biopsy is performed, a small piece of muscle tissue is removed from the patient. Special studies are performed on the tissue. Early in the course of the disease, the muscle shows general abnormalities. Later in the disease, the muscle tissue appears more abnormal. The fat and fibrous tissues that are replacing the muscle fibers are clearly visible.

Another specialized test of muscle function, the electromyogram (EMG) may be performed. The EMG records the electrical activity of a muscle. This test is used to determine whether the symptoms are the result of an underlying muscle problem or a nerve problem. Nerves stimulate muscles to contract. A nonfunctioning muscle

KEY TERMS

Cardiac muscle—The muscle of the heart.

Cardiomyopathy—Measurable deterioration of the heart muscle to contract normally, eventually leading to heart failure.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Dystrophin—A protein that supports muscle strength. Its absence or insufficiency is one of the basic causes of muscular dystrophy.

Germline mosaicism—A condition in which the precursor cells of male sperm or female ova are a mixture of two or more cell lines that are genetically different.

Gowers' sign—An indication of weakness in the proximal muscles of the legs. The child has to use his hands and arms to rise from a squatting or kneeling position.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than ten degrees to the right or left as the doctor faces the patient.

Skeletal muscle—Muscles under voluntary control that attach to bone and control movement.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosomal material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

X inactivation—Sometimes called dosage compensation; a normal process in which one X chromosome in every cell of every female is permanently inactivated.

due to a nerve problem often causes the same symptoms as a nonfunctioning muscle caused by a problem with the muscle.

Genetic testing

Genetic testing is a useful diagnostic tool because the diagnosis can be made without an invasive muscle biopsy. Blood from the person suspected to have muscular dystrophy is analyzed at a specialized laboratory. Genetic testing will confirm that the *DMD* gene is abnormal in most males affected with muscular dystrophy (70% with DMD and 85% with BMD). The disease-causing mutation will be unidentifiable in some males who have muscular dystrophy. Therefore, an abnormal test result is definitive, but a normal test result is not. In these cases, muscle biopsy may be necessary to confirm the diagnosis. Muscle biopsy may be helpful to determine whether a young person with mild symptoms has DMD or BMD even when the diagnosis of muscular dystrophy is established by genetic testing.

The severity of the mutation is correlated to the severity of the disease. For example, mutations that completely eliminate the dystrophin protein are associated with DMD much more often than they are associated

with BMD. Particular mutations have been associated with intellectual impairment. The severity of symptoms can be somewhat predicted by the mutation present.

Even when a mutation in the *DMD* gene has been identified in the affected family member, genetic testing to determine whether or not the females are carriers may not be straightforward.

In some families, a special form of genetic testing called linkage testing may be helpful. Linkage genetic testing can be performed when the diagnosis of Duchenne or Becker muscular dystrophy is certain in more than one family member but no mutation is identified in the *DMD* gene. Linkage testing requires the participation of multiple family members. Unique DNA sequences within the gene and flanking the gene are analyzed to determine whether the sequences are those associated with the deleterious gene or with the normal gene. This method is not 100% accurate.

If a woman knows that she is a carrier, prenatal and preimplantation diagnoses are available. If the specific DMD or BMD mutation has been identified in a family member, genetic testing can be performed on the fetus. The procedures used to obtain fetal cells are chorionic villus sampling (CVS) and amniocentesis. CVS is usually

performed between 10 and 12 weeks of pregnancy, and amniocentesis is usually performed after 16 weeks. Whether amniocentesis or CVS is performed, chromosomal analysis of the fetal cells will show whether the baby is male or female. Linkage testing may also be performed prenatally.

Treatment and management

There is no cure for muscular dystrophy. However, doctors are getting better at treating the symptoms. Many researchers are searching for preventive measures and for a cure. Therapies focus on treating the associated symptoms.

Preventive measures

Exercise and physical therapy help to prevent joint contractures and maintain mobility, although exercise should not be prolonged to the point of exhaustion, as it will lead to increased muscle damage. Swimming and other forms of exercise in water are ideal. Although there is no special diet that will relieve the symptoms of DMD or BMD, calorie restriction may be necessary, as avoiding obesity is important.

Orthopedic devices like standing frames and braces may delay the age at which an affected boy begins to use a wheelchair, and they are often used to treat scoliosis. Motorized wheelchairs and other devices help an affected person who has become disabled to maintain his independence as long as possible. When the cardiac muscles become affected, respiratory care may be necessary. Cardiac function should be evaluated in adult males with BMD even when skeletal muscles are only mildly affected. Some women who are carriers of DMD develop heart disease related to changes in their cardiac muscle. Therefore, surveillance for heart disease should be a consideration for these women.

Experimental therapies

Some researchers are trying to deliver normal dystrophin protein to the muscle. If this were done by gene therapy, a normal copy of the *DMD* gene would be inserted into the muscle cells. This research is in the early stages, but the possibilities give researchers hope that in the future there may be a cure.

A drug developed in Europe called ataluren (Translarna), which is a small-molecule agent, was tested as a treatment for DMD in the European Union in 2010, but phase 2 trials showed that patients did not derive significant improvement from the drug. Nonetheless, the European Medicines Agency approved the drug for sale in Europe in the summer of 2014. Ataluren has not yet been

approved for use in the United States by the Food and Drug Administration (FDA).

Researchers have also experimentally transferred healthy muscle cells into the tissue of individuals with muscular dystrophy; however, this is not a standard treatment. It provides another hope that in the future an effective treatment will be developed.

Claims have been made that a class of medications called corticosteroids slows the progression of muscle destruction in muscular dystrophy. The use of these drugs is controversial. Corticosteroids have not been proven to have a long-term effect. Also, corticosteroids have many serious side effects. Cortisone is a corticosteroid, and prednisone is similar to cortisone.

Discovering the *DMD* gene allowed researchers to create animal models for muscular dystrophy. They have created mice and other animals that have DMD in order to more effectively study the disease and test the efficacy of treatments. Gene therapy has been found effective in mice with DMD and is presently being scaled up for trials in dogs. This development also provides hope for the future.

Prognosis

The prognosis of DMD is confinement to a wheelchair by the age of 12 years and usually death by the early 20s; the average age at death for boys with DMD in the United States is 25. Life expectancy for these patients has been extended into the early 30s for some, however, by recent advances in noninvasive ventilation and careful monitoring of heart-related symptoms. Death usually results from cardiopulmonary problems.

The prognosis for BMD varies. Some individuals with BMD require a wheelchair after 16 years of age, but others remain ambulatory into middle adulthood.

Some mildly affected individuals never require a wheelchair. The average life expectancy for BMD is the mid-40s, although some men diagnosed with BMD have lived into their early 60s. Both conditions are progressively debilitating.

Because DMD is a relatively common and severe condition, many people very actively promote further funding, research, and support of affected individuals. Associations to help families with muscular dystrophy have chapters all over the world. Families and researchers are hopeful that the genetic discoveries of the 1990s will lead to new treatments and cures in the new millennium. However, the obstacles between understanding the pathogenesis of a disease and creating an effective treatment are large. This is especially true of muscular dystrophy.

Dyschondrosteosis

Definition

Dyschondrosteosis (DCO) is a genetic form of dwarfism characterized by short forearms, short lower legs, normal-sized torso, normal-sized head, and a wrist and arm bone abnormality called Madelung deformity.

Description

DCO was first described by doctors André Léri and Jean Weill in 1929. Léri and Weill described patients with dwarfism characterized by short lower legs, normal-sized torso, and a specific wrist and arm bone abnormality called Madelung deformity. Other names for DCO include Léri-Weill dyschondrosteosis (LWD), Léri-Weill syndrome (LWS), Léri-Weill disease, mesomelic dwarfism-Madelung deformity, Lamy-Bienefeld syndrome, Langer's syndrome, Langer's mesomelic dwarfism, and Langer's mesomelic dysplasia.

Genetic profile

DCO is a pseudoautosomal dominant condition caused by a change or mutation in one of two genes called *SHOX* and *SHOY*. The *SHOX* gene is located on the short arm of the X chromosome in the pseudoautosomal region (Xpter-p22.32). *SHOY* is located on the Y chromosome in the pseudoautosomal region (Ypter-p11.2). Chromosomes are the structures found in all cells that contain genes. In each cell, there are 46 chromosomes, which come in 23 pairs. One member of each pair comes from the mother, and the other comes from the

father. The first 22 pairs are called autosomes and are the same in males and females. The last pair of chromosomes is the sex chromosomes, X and Y. Females have two X chromosomes, and males have one X chromosome and one Y chromosome. On the sex chromosomes, there are regions that contain the same genes. These regions are called the pseudoautosomal regions because the genes in those regions behave as if they were on an autosomal chromosome and are the same in males and females. Seventy percent of families affected by DCO have a mutation in the *SHOX* gene. The remaining families have a mutation in the *SHOY* gene, or possibly another gene related to the *SHOX* and *SHOY* genes that leads to problems in bone development.

When DCO is caused by a mutated *SHOX* or *SHOY* gene, it is inherited through the family in a pseudoautosomal dominant pattern. In a pseudoautosomal dominant condition, only one nonworking copy of the gene for a particular condition is necessary for a person to experience symptoms of the condition. If a parent has a pseudoautosomal dominant condition, there is a 50% chance for each child to have the same or similar condition. DCO can also appear in an individual for the first time and not be found in the affected individual's parents. An individual who is the first member of the family to be affected by DCO passes DCO to his or her children in a pseudoautosomal dominant pattern of inheritance. Accordingly, the individual who has *de novo* (new) DCO has the same 50% chance to have affected children.

Individuals inheriting the same nonworking gene in the same family can have very different symptoms. For example, some family members affected by DCO may be affected by proportional dwarfism with no visible arm bone deformity, while other family members may have very short (mesomelic) arms and legs and severe Madelung deformity. The difference in physical findings within the same family is known as variable penetrance, or intrafamilial variability.

Studies have suggested that another form of severe dwarfism called Langer mesomelic dysplasia is the result of inheriting two copies of the mutated gene that causes DCO. Langer mesomelic dysplasia is characterized by severe short stature with underdeveloped or missing arm bones.

Demographics

DCO is a rare genetic condition. The ethnic origins of individuals affected by DCO are varied, and DCO is not more common in any specific ethnicity. There are more females than males affected by DCO, and females affected by DCO appear to be more severely affected than males.

Signs and symptoms

Most individuals affected by DCO have short stature, short lower legs and forearms (mesomelia), normal head size, normal torso size, and a specific form of arm bone abnormality called Madelung deformity. Madelung deformity occurs when one of the bones of the forearms (the radius) is short and bends toward the shortened and partially dislocated and bent ulna (subluxation), which causes the wrist to be shifted toward the thumb. Affected individuals may also exhibit abnormalities of the large bone of the upper arm (humerus); abnormal bony growths projecting outward from the surface of the shin bones (exostoses of the tibia); unusually short, broad bones in the fingers and toes; and abnormalities of the hipbones. One study found that some males have overdeveloped muscles (or muscular hypertrophy). There is also some evidence that conductive hearing loss may be found as a symptom in some individuals. Depending on the individual, DCO can result in severe to very mild symptoms (variable expression). Females affected by DCO tend to have more severe symptoms, including a more frequent occurrence of Madelung deformity.

Some individuals affected by DCO can also be affected by other symptoms not usually considered part of the DCO features. These features, such as intellectual disability, Hodgkin's lymphoma, kidney disease, and skin disorders, are believed to be caused by errors in genes close to the mutated *SHOX* or *SHOY* gene. Based on a finding of two sisters with dyschondrosteosis who both developed Hodgkin's lymphoma in late adolescence, it was suggested that a gene that increased the risk to develop Hodgkin's lymphoma may be located very near to the *SHOX* and *SHOY* genes. Individuals affected by Hodgkin's lymphoma, or other unusual symptoms, and DCO are most likely affected by an Xp22.3 contiguous gene syndrome. The name refers to a syndrome caused by the deletion or incorrect working of several genes found side-by-side on the X chromosome.

Diagnosis

Diagnosis of DCO is usually made from physical examination by a medical geneticist and x-rays of the legs and arms. The characteristic Madelung deformity of the arms is generally not identified in children through physical exam, but the first signs of the Madelung deformity, like forearm bone bowing, can be identified by x-rays in children aged two to five years. The condition's characteristic bone abnormalities become more pronounced during adolescence. Clinical genetic testing for DCO is now available to examine portions of the *SHOX* or *SHOY* genes to look for a mutation that would cause the gene not to work correctly. Although clinical testing is

KEY TERMS

Madelung deformity—A forearm bone malformation characterized by a short forearm, an arched or bow-shaped radius, and dislocation of the ulna, resulting in wrist abnormalities.

Mesomelia—Shortness of the portion of arm connecting the elbow to the wrist or forearm.

Pseudoautosomal dominant inheritance—The pattern of inheritance for a disorder caused by genes in the pseudoautosomal regions of the sex chromosomes. Individuals only require one mutated or nonworking copy of a gene to have signs and symptoms of the disorder. Affected individuals have a 50% chance to have an affected child with each pregnancy.

available, testing cannot identify all mutations causing DCO. Physical exams and x-rays may diagnosis an individual without an identifiable mutation *SHOX* or *SHOY*. In families in which a mutation is identified, prenatal diagnosis through amniocentesis is available.

Treatment and management

DCO is a genetic disorder and does not have a specific therapy that removes, cures, or fixes all signs of the condition. Treatment and management of DCO focuses on treatment of specific symptoms of the disorder. Some progress in increasing height has been made by growth hormone (GH) supplementation in affected children. However, hormone supplementation causes disproportionate growth, leading to longer arms and trunk and shorter legs. The Madelung deformity found in many individuals with DCO can be treated surgically by addressing the deforming bone ligaments, correcting the abnormal position of the lower arm bones, and equalizing the length of the arms' radius and ulna bones. Operative treatment for the Madelung deformity is indicated for pain relief and appearance of the arm and wrist but may not greatly improve the wrists' range of motion. Individuals with conductive hearing loss may wish to consider surgery or hearing aids to improve hearing.

Prognosis

The symptoms of individuals affected by DCO can be severe or mild, and prognosis depends on the severity

of the symptoms. Severe Madelung deformity may cause pain in adolescence that is most often relieved through surgery. Individuals affected by DCO are of short stature and may need adjustments in their living space to optimize their living conditions.

Dysplasia

Definition

"Dysplasia" comes from the Greek *dys*, meaning "difficult" or "disordered," and *plassein*, meaning "to form." Dysplasia is the abnormal or disordered organization of cells into tissues. All abnormal tissue formations

A baby girl wearing an apparatus for hip dysplasia, lying on her sister. (Anastasia Tveretina/Shutterstock)

are classified as dysplasias, including a large number of genetic disorders.

Description

Dysplasias—or dysplastic tissues—have an abnormal cellular organization. Dysplasias can be caused by an underlying genetic disorder due to a mutation (change) in a gene or result from injury, infection, toxins, or other environmental factors. Some dysplasias develop into cancer. Dysplasias can be localized, with the tissue abnormality confined to a single area or body part, or generalized, affecting multiple parts of the body. There are several hundred genetic dysplasias resulting from inherited or acquired gene mutations. In many cases, the responsible genes and mutations are known. Genetic dysplasias tend to be generalized, with malformations or abnormalities throughout the body, depending on the particular tissue organization defect and the organs that arise from the dysplastic tissue, since structural problems associated with generalized dysplasias usually begin during embryonic development. Two major types of dysplasias—skeletal and ectodermal—are caused by underlying genetic disorders. There are no specific treatments for most forms of genetic dysplasia.

Skeletal dysplasias

Skeletal dysplasias affect the growth, organization, and development of the bony skeleton. They are always genetic disorders, but their effects vary greatly. A mild skeletal dysplasia may cause short stature with no other complications. Other skeletal dysplasias may severely reduce height, causing dwarfism with disproportion and other bone deformities. The most severe skeletal dysplasias are fatal before or soon after birth. The many types of skeletal dysplasias include achondroplasia, hypochondroplasia, thanatophoric dysplasia, achondrogenesis,

diastrophic dysplasia, atelosteogenesis, spondyloepiphyseal dysplasia, Kniest dysplasia, Stickler syndrome, pseudoachondroplasia, and metaphyseal dysplasia.

Achondroplasia. Achondroplasia, the most common form of short-limbed dwarfism, is a highly recognizable skeletal dysplasia that occurs in 1 in 15,000–40,000 newborns. Although “achondroplasia” means literally “without cartilage formation,” the disorder is caused by the failure of cartilage to be converted into bone, especially in the long bones of the arms and legs. In addition to short stature, achondroplasia causes a large head, characteristic facial features, and disproportionately short arms and legs. It is caused by a mutation in a single gene called fibroblast growth factor receptor 3 (*FGFR3*). The *FGFR3* gene produces a protein that is important for the development and maintenance of both bone and brain tissue. Almost all cases of achondroplasia are caused by one of two mutations in the *FGFR3* gene. These mutations appear to cause an overactive *FGFR3* protein that disrupts skeletal development. These are called “gain-of-function” mutations. Gain-of-function mutations in *FGFR3* are also responsible for other skeletal dysplasias, such as hypochondroplasia and thanatophoric dysplasia.

Achondroplasia is an autosomal dominant condition, meaning that a mutation in just one of the two copies of the *FGFR3* gene is sufficient to cause the disorder. Although some cases of achondroplasia are inherited from one or both parents, about 80% of cases are caused by sporadic, or *de novo*, mutations that occur in the father’s sperm cell, the mother’s egg cell, the fertilized egg or embryo, or during early fetal development. These new mutations are observed more frequently in children born to older fathers. Children who inherit two altered *FGFR3* genes, one from each parent, typically have a severe form of the disorder with extremely short bones and an underdeveloped rib cage. They are usually still-born or die of respiratory failure shortly after birth.

Hypochondroplasia. Hypochondroplasia is a short-limbed dwarfism similar to achondroplasia, but it is typically less severe. It results in varying degrees of short stature, a long torso, and disproportion of limbs. It is believed to occur with about the same frequency as achondroplasia, but people with mild symptoms may never be diagnosed. About 70% of cases are, like achondroplasia, caused by mutations in the *FGFR3* gene that appear to cause the production of an overactive protein. Like achondroplasia, hypochondroplasia is an autosomal dominant disorder. Most children with hypochondroplasia have average-sized parents. A few cases are inherited from one or both parents, but most cases result from a new sporadic mutation in the *FGFR3* gene.

Thanatophoric dysplasia. Thanatophoric dysplasia is a severe disorder resulting in extremely short limbs and extra folds of skin on the arms and legs. The chest is narrow, the ribs are short, and the lungs are underdeveloped. The head is enlarged, the forehead is large, and the eyes are wide-spaced and prominent. Most babies with thanatophoric dysplasia are stillborn or die shortly after birth of respiratory failure. The disorder occurs in 1 in 20,000–50,000 newborns, and type I is more common than type II. Thanatophoric dysplasia is not known to be inherited; rather, it is caused by new sporadic gain-of-function mutations in the *FGFR3* gene.

Ectodermal dysplasias

Ectodermal dysplasias affect the growth and development of tissues derived from the early outer layer of embryonic tissue known as the ectoderm. Tissues derived from the ectoderm include hair, nails, skin, sweat glands, and teeth. People with ectodermal dysplasias display abnormalities in at least two ectoderm derivatives. The effects of ectodermal dysplasia (ED) range from mild to severe. There are more than 150 different types of ED because so many tissues in the body are derived from the ectoderm. ED is divided into two major groups based on the presence or absence of normal sweating. Sweat production is normal in hidrotic types and reduced in hypohidrotic types. Hypohidrotic types with reduced or absent sweating are generally more severe disorders. Many different gene mutations are known to cause ED.

Hypohidrotic ED. Hypohidrotic ED is the most common form of ED, affecting at least 1 in 17,000 people worldwide. Most people with this disorder have fewer than normal sweat glands or sweat glands that do not function properly. They are not able to control their body temperature well due to reduced sweating. They may also be unable to form tears normally. They often have small or missing teeth, eyebrows, and eyelashes. Head hair is usually sparse, but fingernails are normal.

Hypohidrotic ED is caused by mutations in the *EDA*, *EDAR*, and *EDARADD* genes, which produce proteins that work together during embryonic development, forming part of a signaling pathway that is essential for proper interactions between the ectoderm and the mesoderm (the middle layer of embryonic tissue below the ectoderm). Although hypohidrotic ED has several different inheritance patterns, most cases are caused by mutations in the *EDA* gene, which is on the X chromosome and is inherited in an X-linked recessive pattern. This means that it usually affects males because they have only one X chromosome. Females, who have two X chromosomes, do not develop hypohidrotic ED unless they inherit a mutated *EDA* gene on the X chromosome from each parent. The presence of a normal *EDA* gene on one X chromosome

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Cartilage—A tough elastic tissue that is a building block for bone.

De novo mutation—A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

Ectoderm—The outermost of the three embryonic cell layers, which later gives rise to the skin, hair, teeth, and nails.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Skeletal dysplasia—A group of syndromes consisting of abnormal prenatal bone development and growth.

Tissue—A group of similar cells that work together to perform a particular function. The four basic types of tissue are muscle, nerve, epithelial, and connective tissues.

Vertebra—One of the 23 bones that comprise the spine. Vertebrae is the plural form.

X-linked recessive inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male, passed from a female who has the gene on one of her X chromosomes. She is referred to as an unaffected carrier.

is sufficient to prevent the disorder. However, some females with one mutated *EDA* gene have mild symptoms of the disorder. Mutations in the *EDAR* and *EDARADD* genes that cause hypohidrotic ED affect males and females equally because the genes are located on autosomal chromosomes rather than the X sex chromosome. Hypohidrotic ED is also known as Christ-Siemens-Touraine syndrome (CST).

Clouston syndrome. Clouston ectodermal dysplasia is a hidrotic (sweating) ED that causes hair, nail, and skin abnormalities. The teeth and sweat glands are normal. People with this form of ED have partial to total baldness, severely abnormal fingernails and toenails, and darkly

pigmented areas of skin, especially over the joints. They have underdeveloped eyebrows and eyelashes and may be born with teeth. They may also have thickened skin on the soles of their feet and the palms of their hands. Intelligence is usually normal, but some cases involve intellectual disability and strabismus (unbalanced eye muscles that affect binocular vision). The prevalence of Clouston syndrome is unknown, although it has been reported in many different populations and is particularly common in people of French Canadian descent.

Clouston syndrome is caused by mutations in the *GJB6* gene that produces a protein called gap junction beta 6, usually known as connexin 30. Connexin proteins form channels between cells called gap junctions. Nutrients, ions, and signaling molecules move between cells via gap junctions. Connexin 30 forms gap junctions that transport potassium ions and some small molecules. It is involved in the growth and development of various tissues in the body, especially the skin on the palms of the hands and soles of the feet, hair follicles, and nail beds. Clouston syndrome-causing mutations in the *GJB6* gene change single amino-acid building blocks in the connexin 30 protein, which leads to abnormal growth, division, and maturation of skin, nail, and hair follicle cells. These mutations are inherited in an autosomal dominant pattern, meaning that only one altered gene, usually inherited from an affected parent, is sufficient to cause Clouston syndrome. Each child of an affected person has a 50% risk of inheriting the mutated gene and having Clouston syndrome. Some cases result from new sporadic mutations in the *GJB6* gene in people with no family history of the disorder.

Dystonia

Definition

Dystonia is a group of complex disabling neurological movement disorders. While the disorders vary in their symptoms, causes, progression, and treatment, the dystonias are characterized by involuntary muscle contractions

and spasms that result in abnormal postures and movements. Focal dystonias—which affect a single part of the body, such as the face, arms, or vocal chords—are the most common.

Description

Dystonia is generally considered to be a group of movement disorders with a variety of symptoms. The most common characteristic of dystonia is twisting, repetitive, and sometimes painful movements that affect specific parts of the body, such as the arms, legs, trunk, neck, eyelids, face, or vocal cords. The term “dystonia” was first coined in 1911 by Hermann Oppenheim, an eminent German neurologist, in reference to a childhood-onset syndrome he termed dystonia musculorum deformans. This condition, now known as idiopathic torsion dystonia, was noted to run in families and, although presumably inherited, was only recently proven to have a genetic cause. There is, however, considerable variability in the manifestation of clinical symptoms of dystonia, which has led to a number of different and often confusing attempts to classify the dystonias. In 2012 an international panel of experts on the dystonias was formed by the Dystonia Medical Research Foundation, the European Dystonia Cooperation in Science and Technology Action, and the Dystonia Coalition. The panel proposed a revised classification scheme in 2013 in which the dystonias are classified along two axes: clinical symptoms (age of onset, distribution in the body, temporal pattern, and associated features); and etiology or cause.

The current age-based classification has five categories: infancy (birth to two years of age), childhood (3–12 years), adolescence (13–20 years), early adulthood (21–40 years), and late adulthood (over 40 years).

“Distribution” refers to the location of the symptoms in the patient’s body. Dystonia may be described as focal (localized to one body part), segmental (involves adjacent body parts), multifocal (two or more body regions that are not adjacent are involved), generalized (symptoms begin in an arm or a leg and eventually affect the rest of the body), and hemidystonia (symptoms affect only one side of the body). Spasmodic torticollis (cervical dystonia), which affects the head and neck, is the most common adult form of focal dystonia, followed by blepharospasm (eyelids), spasmodic dysphonia (larynx), and limb dystonias (hands).

“Temporal pattern” refers to the time of day that the symptoms are most noticeable: the dystonia may be persistent (occurring throughout the day), action-specific (occurs only when the patient is performing a certain action, such as writing or playing a musical instrument), or paroxysmal (resulting from a specific trigger). The phrase “associated features” refers to whether the

disorder is an isolated dystonia (there are no other motor symptoms except tremor); combined dystonia (formerly called dystonia-plus; in combined dystonia the dystonia occurs together with another movement disorder like Parkinsonism or myoclonus); or complex dystonia (in which the dystonia coexists with other neurological or systemic illnesses). The complex dystonias include dystonia coexisting with neurodegenerative disorders (Huntington’s disease, Rett syndrome, and dentatorubral-pallidolusian atrophy), disorders of copper metabolism (Wilson’s disease), disorders of purine metabolism (Lesch-Nyhan syndrome), mitochondrial disorders, encephalopathies (Aicardi-Goutières syndrome), and many others.

When dystonia is classified by cause, it is defined as either idiopathic (of unknown origin), hereditary (inherited), or acquired. Acquired dystonia may be caused by birth injury, head trauma, environmental toxins, certain infections, or stroke.

Genetic profile

At least 25 different forms of dystonia have been traced to specific genes. Most are inherited in an autosomal dominant pattern, although at least two are inherited in an autosomal recessive pattern, and one is inherited in an X-linked pattern. The classification of the hereditary dystonias was revised by the international panel to simplify and organize what had become an unwieldy list of genetic mutations that included errors in gene identification in addition to genetic loci that were unconfirmed. The present list of monogenic (single-gene) dystonias is grouped under the general headings of isolated and combined dystonias.

Isolated dystonias

There are three dystonias in this group; all three are inherited in an autosomal dominant pattern:

- Early-onset generalized dystonia (also called early-onset torsion dystonia), caused by a mutation in the *TOR1A* gene on the long arm of chromosome 9 at 9q34.
- Adolescent-onset dystonia of mixed type, caused by a mutation in the *THAPI* gene on the short arm of chromosome 8 at 8p11.21.
- Adult-onset cranial-cervical dystonia, caused by a mutation in the *GNAL* gene on the short arm of chromosome 18 at 18p11.21.

Combined dystonias

There are three subgroups classified as combined dystonias, as follows:

- Dystonia plus Parkinsonism. There are five dystonias in this subgroup with different patterns of inheritance: (1) X-linked dystonia-Parkinsonism, caused by a mutation in the *TAF1* gene on the long arm of the X chromosome

at Xq13; (2) autosomal dominant dopa-responsive dystonia, caused by a mutation in the *GCH1* gene on the long arm of chromosome 14 at 14q22.1-q22.2; (3) autosomal recessive dopa-responsive dystonia, caused by a mutation in the *TH* gene on the short arm of chromosome 11 at 11p15.5; (4) autosomal recessive dopa-responsive dystonia and cognitive impairment, caused by a mutation in the *SPR* gene on the short arm of chromosome 2 at 2p13.2; and (5) autosomal dominant rapid-onset dystonia-Parkinsonism, caused by a mutation in the *ATPIA3* gene on the long arm of chromosome 19 at 19q12-q13.2.

- **Dystonia plus myoclonus:** This dystonia is inherited in an autosomal dominant pattern and is caused by a mutation in the *SGCE* gene on the long arm of chromosome 7 at 7q21.
- **Paroxysmal dystonia plus other dyskinesia.** There are three dystonias in this subgroup, all inherited in an autosomal dominant pattern: (1) paroxysmal non-kinesigenic dyskinesia, caused by a mutation in the *MRI* gene on the long arm of chromosome 2 at 2q35; (2) paroxysmal kinesigenic dyskinesia, caused by a mutation in the *PRRT2* gene on the short arm of chromosome 16 at 16p11.2; and (3) paroxysmal exertion-induced dyskinesia, caused by a mutation in the *SLC2A1* gene on the short arm of chromosome 1 at 1p35.

Demographics

As of 2021, dystonia affected an estimated 300,000 people in the United States and Canada, affecting both sexes, all age groups, and all races and ethnic groups. Early-onset idiopathic torsion dystonia has a higher frequency among Ashkenazi Jews—Jews of Eastern European ancestry—affecting 1 in 3,000 to 9,000 people in this population.

Dystonia is the third most common movement disorder after Parkinson's disease and tremor.

Signs and symptoms

Researchers believe that dystonia is caused by a malfunction in the basal ganglia, a group of nuclei (clumps of nerve cells) in the forebrain involved in regulating voluntary and involuntary movement. Some researchers also think that abnormalities in the level of dopamine and other neurotransmitters in the brain may play a part in causing the dystonias. Acquired dystonia may occur due to head trauma, stroke, certain infections and diseases (e.g., Wilson disease, multiple sclerosis), reactions to certain neuroleptic or antipsychotic drugs (e.g., haloperidol or chlorpromazine), birth injury, or heavy-metal or carbon monoxide poisoning. About half of dystonia cases, however, have no connection to disease or injury and are either idiopathic or hereditary.

Early symptoms of dystonia may include deterioration in handwriting or musical performance, foot cramps, tremor, voice or speech difficulties, and a tendency for

one foot to pull up or drag while walking. Initially, the symptoms may be very mild and noticeable only after prolonged exertion, stress, or fatigue. Over a period of time, the symptoms may become more noticeable and widespread. The symptoms may begin at any point in the patient's life from infancy to late adulthood. In general, the earlier the onset of symptoms, the greater the chance that the disease will progress with advancing age.

Dystonia symptoms also depend on the body part affected. Dystonia localized to the face may involve repetitive blinking (blepharospasm), tongue protrusion, or jaw clenching. Blinking can become so severe that the patient cannot see due to inability to open the eyes. Dystonia affecting the neck may lead to sustained flexion, extension, or twisting postures of the neck known as spasmodic torticollis. Some dystonias are task-specific and arise only during the performance of certain tasks like writing, typing, or playing instruments. The progression of these symptoms can lead to severe disability and inability to perform daily work. Generalized dystonia, the most severe form, can present as twisting movements of the head, trunk, and arms, completely disabling the affected individual. Dystonia can often be associated with tremor in the affected body part. All forms of dystonia impair normal movement and daily function to some degree. Dystonia can be worsened by stress and anxiety, but it may be relieved by relaxation and sleep.

Diagnosis

As of 2021, there was no specific diagnostic laboratory test for dystonia, although blood, urine, and cerebrospinal fluid tests may be ordered to rule out infections, drug reactions, or other organic disorders of the nervous system. An MRI of the brain may be performed to look for evidence of stroke or a structural abnormality in the brain causing the symptoms. Imaging studies are not, however, useful in detecting abnormal patterns of activity in the basal ganglia or abnormalities in the level of neurotransmitters in the brain.

The diagnosis is often based on clinical signs and symptoms, and its accuracy depends on the examiner's experience with movement disorders. Diagnosis is often complicated because the signs of dystonia are similar to those of other disorders; many of the dystonias have overlapping phenotypes even though they may have different genetic or other causes, and the involuntary muscle contractions are often incorrectly attributed to emotional stress, athletic injuries, stiff neck, dry eyes, tics, or psychogenic or neurological disorders. The doctor will usually take a careful patient history and family history. If the family history suggests an inherited form of dystonia, molecular genetic tests may be ordered. Genetic tests are available for most of the hereditary forms of dystonia.

KEY TERMS

Basal ganglia—An area in the forebrain that contains seven nuclei (clusters of nerve cells) responsible for initiating and controlling voluntary movement along with procedural learning and some habitual actions.

Blepharospasm—An abnormal involuntary twitching or closing of the eyelid. It is the second most common type of focal dystonia.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Dyskinesia—Impairment or difficulty in performing voluntary movements, usually resulting in jerky or interrupted movements.

Genotype—The genetic makeup of an individual organism or cell.

Idiopathic—Of unknown origin.

Levodopa—A chemical produced naturally in the body that is a precursor to such neurotransmitters as serotonin and epinephrine. It is also manufactured as

a drug and used to treat Parkinson's disease and the dopa-responsive dystonias.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Myoclonus—Twitching or spasms of a muscle or an interrelated group of muscles.

Parkinsonism—A symptom complex that includes tremor, abnormally slow movements (bradykinesia), difficulty maintaining one's balance, and muscle rigidity. Parkinsonism should not be confused with Parkinson's disease (PD); it can occur as a group of symptoms in neurological disorders other than PD.

Phenotype—An observable characteristic or trait of an organism as determined by its genetic makeup (genotype) and its interactions with the environment.

Spasmodic torticollis—A painful chronic neurological disorder in which involuntary contractions of the neck muscles cause the person's head to twist or turn from side to side or upward and downward. It is also called cervical dystonia.

Tremor—Involuntary rhythmic back-and-forth movements involving one or more parts of the body. Tremor is most commonly seen in the hands but can affect almost any part of the body.

One helpful characteristic in differentiating dystonic movements from those caused by other disorders is the timing of the movements. Dystonic movements tend to increase during activity, nervousness, and emotional stress, and they usually disappear during sleep.

Treatment and management

There was no cure for dystonia as of 2021. However, such symptoms as spasms and pain can usually be managed with a combination of treatments. Treatment for dystonia is usually directed toward management of the symptoms and depends on the type of dystonia. Dystonia associated with or caused by such known etiologies as drugs, Wilson's disease, or dopa-responsive dystonias may be improved by treating the underlying disease with resolution of symptoms.

Traditional

No one treatment has proven universally effective for dystonia. A physician's approach to treatment is typically three-tiered, encompassing oral medications, injections of therapeutic agents (botulinum toxin) directly into dystonic

muscle, and surgery. Surgery, which involves cutting nerves and muscles or placing a lesion in the basal ganglia to reduce movement, is usually reserved for the most severe cases.

The cause and location of a patient's dystonia will play a factor in the treatment methods chosen by the physician. Patients with focal dystonia often respond best to targeted methods—such as injections of botulinum toxin or surgery—while patients with generalized dystonia may first need to be treated with oral medications to alleviate the multiple symptoms.

Drugs

Various oral medications are available for the symptomatic treatment of dystonia; however, there is no single drug that works for all patients. Among the medications that can be tried are muscle relaxants. Some patients with symptoms of early-onset dystonia may respond dramatically to levodopa, a drug used to treat Parkinson's disease. Dystonias that respond to treatment with levodopa are called dopa-responsive dystonias. Anticholinergics, dopamine-depleting agents, benzodiazepines (particularly diazepam), baclofen, or atypical

antipsychotics may be tried as well. Almost all these medications have side effects, however, ranging from drowsiness and short-term memory loss to weight gain, dry mouth, and constipation.

Botulinum toxin (Botox) is effective in many patients with dystonia; however, symptom relief is only temporary (about three to six months), necessitating repeated injections. There are some risks; for example, the botulinum toxin may leak from the injection site into nearby muscle groups or cause temporary paralysis at the injection site. In addition, about 15% of patients eventually develop immunity to Botox.

Deep brain stimulation

Deep brain stimulation (DBS) is an increasingly recommended treatment for severe dystonia and for patients who cannot tolerate the side effects of medications. It involves the surgical implantation of small electrodes in the brain connected by wires to a battery-powered pulse generator located beneath the skin over the collarbone or the abdomen. The pulse generator sends electrical impulses into the electrodes implanted in the areas of the brain that control movement. DBS was approved by the FDA for the treatment of dystonia in 2003. Recent improvements in both the device and method of implantation have led to high rates of success in patients with dystonia.

DBS should be performed only under the supervision of a team of specialists, including a neurologist, a psychiatrist, and a neuropsychologist, as well as a neurosurgeon. The settings of the DBS require careful monitoring and adjustment following implantation. Like medications for dystonia, DBS also carries risks, including depression and hallucinations.

Prognosis

The prognosis of dystonia depends on the body distribution, age of onset, and the cause. The initial site of symptoms may predict the prognosis. Patients with

symptoms that start in the leg have a higher likelihood (90%) of progression to other body parts and the development of generalized dystonia. Patients with symptoms starting in the neck and that are later in onset have a much lower likelihood of spread. Most focal dystonias respond to medications or botulinum toxin. Refractory and generalized dystonias may require surgical management. Most patients have a normal life expectancy with normal intelligence and cognitive skills, although they may have ongoing disabling symptoms.

Ectodermal dysplasia

Definition

The ectodermal dysplasias (EDs) are a group of over 200 hereditary conditions characterized by abnormalities of the skin, hair, teeth, fingernails and toenails, and sweat glands. First described in 1848, the EDs were given their present name by A. A. Weech in 1929.

Description

The ectodermal dysplasias are a group of congenital nonprogressive disorders characterized by abnormalities of the skin and other tissues derived from the ectoderm. All EDs have a genetic etiology. The ectoderm is the outermost germ layer of the developing embryo, which gives rise to the nervous system, hair, teeth, nails, and skin. More than 200 different ED conditions have been described in the medical literature, and their number keeps increasing. The most common of these is hypohidrotic ED, also known as HED and Christ-Siemens-Touraine syndrome, which may account for up to 80% of all EDs.

Other EDs include ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome, hidrotic ectodermal dysplasia (Clouston syndrome), Hay-Wells syndrome, incontinentia pigmenti, Rapp-Hodgkin syndrome, tricho-dento-osseous syndrome, and tooth-nail (Witkop) syndrome. Each of these conditions appears to account for 1%–4% of all ectodermal dysplasias.

Most EDs are associated with sparse hair that has abnormal texture. The hair may appear thin, dry, and brittle. In some cases, premature balding may occur.

The teeth of patients with ED are typically abnormal and reduced in number. A characteristic conical and sharply pointed tooth shape is often present. In some cases, the majority of teeth are missing.

In some EDs, the fingernails and toenails may be absent or abnormally formed. The nails may be

thickened, thinned, brittle, or display unusual ridging or pitting.

The skin may be thin, show abnormal pigmentation, and be prone to eczema (a condition of dry skin characterized by inflammation and itching). The nasal and respiratory passages may be dry, leading to abnormal discharges and increased infections. In hypohidrotic ED, the sweat glands are reduced in number, which may lead to dangerous hyperthermia (high body temperature).

Other abnormalities that may occur in the ectodermal dysplasia conditions include amastia (absent mammary glands), cleft lip and/or palate, ectrodactyly (split hand or split foot), and abnormal bands of skin in the mouth or connecting the eyelids.

Many individuals with ED have normal cognitive function. A minority of cases, however, may involve some degree of intellectual disability. In the case of hypohidrotic ED, untreated hyperthermic episodes can lead to brain damage and cognitive impairment.

Genetic profile

There is no inheritance pattern common to all the EDs. Some are inherited in an autosomal dominant pattern, meaning that one copy of the mutated gene in each cell is sufficient to cause the disorder; some in an autosomal recessive pattern, meaning that two abnormal genes are needed in order for a person to have the disorder. Some are X-linked dominant, some are X-linked recessive, and some result from *de novo* mutations. In addition, not all mutations that cause EDs have been identified. About 80 of the more than 200 known EDs had been traced to specific genes as of 2021.

One of the complications in understanding the genetic profiles of the EDs is that there is no universally accepted classification of the EDs, and the first classification systems were based on clinical symptoms. The earliest classification system divided the EDs into two groups according to the complete absence (anhidrotic) or severe deficiency (hidrotic) of function in the patient's eccrine

glands. The eccrine glands are the glands that produce the water-based sweat that is the primary cooling mechanism in humans. In 1982 two Brazilian specialists attempted to classify the EDs into four categories according to whether their primary symptoms were related to the hair, teeth, nails, or eccrine glands. Another clinical classification system divides the EDs into two groups based on whether the ED is a pure disorder (the defects involve only ectodermal structures) or whether it is complex—that is, part of a syndrome that includes other anomalies.

Starting in 2009 with the discovery of the genetic mutations associated with EDs, some researchers suggested reclassifying them according to the underlying functional defect. One proposal suggested four groups: (1) EDs resulting from defective cell-to-cell signaling, (2) EDs resulting from faulty cell adhesion, (3) EDs associated with defects in development, and (4) EDs marked by other functional defects. Other experts suggested a

slightly different fourfold classification. One obvious difficulty with a classification based on genetics is that many of the genes associated with EDs are still unknown. In any case there was no classification system as of 2021 that was completely satisfactory, although it is expected that any forthcoming classification will combine both clinical symptoms and molecular genetic information.

Hypohidrotic ED (HED) has one of the most complicated patterns of ED inheritance, as it is caused by mutations in three different genes: *EDA*, *EDAR*, and *EDARADD*. These genes provide instructions for making proteins required for signaling between two cell layers: the ectoderm and the mesoderm. In the early embryo, these cell layers form the basis of development for many organs and tissues, including several structures required for the formation of skin, hair, nails, teeth, and sweat glands. Mutations in the *EDA*, *EDAR*, or *EDARADD* genes accordingly impair normal interactions between

the ectoderm and the mesoderm and the normal development of hair, sweat glands, and teeth, leading to the characteristic features of HED.

Most commonly, HED results from *EDA* mutations. The defective gene, located on the X chromosome (Xq12-q13.1), is inherited in an X-linked recessive pattern. Since males have only one X chromosome, one altered copy of the gene in each cell is enough to cause ED. Females, however, have two X chromosomes, so a mutation must be present in both copies of the gene to cause the dysplasia. Carriers of hypohidrotic ED experience some ED symptoms in about 70% of cases. Symptoms are usually mild, such as a few missing teeth, sparse hair, and abnormal sweat gland function. Hypohidrotic ED less commonly results from defective *EDAR* or *EDARADD* genes. The *EDAR* gene is on the long arm of chromosome 2 at 2q13, and the *EDARADD* gene is on the long arm of chromosome 1 at 1q42.3. *EDAR* mutations can have an autosomal dominant or autosomal recessive pattern of inheritance, and *EDARADD* mutations have an autosomal recessive pattern of inheritance. Autosomal dominant inheritance means that one copy of the mutated gene in each cell is sufficient to cause the disorder. Autosomal recessive inheritance means that two copies of the gene in each cell are mutated. The parents of an individual with an autosomal recessive disorder are most often carriers of one copy of the mutated gene but do not show ED symptoms.

Another ED that may be caused by mutations in two different genes inherited in two different patterns is anhidrotic ectodermal dysplasia with immune deficiency, or EDA-ID. EDA-ID may result from mutations in the *NFKBIA* gene on the long arm of chromosome 14 at 14q13, which are inherited in an autosomal dominant fashion, or from mutations in the *IKBKG* gene on the X chromosome at Xq28, which are inherited in an X-linked recessive pattern.

Incontinentia pigmenti is caused by chromosomal rearrangements disrupting the Xp11 region (type I incontinentia pigmenti) or by the *IKBKG* gene mapping to Xq28 (type II or familial incontinentia pigmenti). Both forms appear to be lethal in males, as nearly all affected living patients (97%–98%) are female.

The molecular genetics of the ED conditions are extremely challenging, due to the similar features of the many ED variants and their genetic heterogeneity (different genetic alterations producing identical physical features). An example of an ED that results from genetic mutations in any of four different genes is cranioectodermal dysplasia, an ED in which patients have abnormally shaped skulls, prominent foreheads, and other abnormal facial features, as well as the sparse hair, misshapen teeth,

abnormal fingernails, and dry skin that are found in other EDs. Cranioectodermal dysplasia may result from mutations in the *IFT43* gene on the long arm of chromosome 14 at 14q24.3, the *IFT122* gene on the long arm of chromosome 3 at 3q21, the *WDR19* gene on the short arm of chromosome 4 at 4p14, and the *WDR35* gene on the short arm of chromosome 2 at 2p24.1. Mutations in all four genes associated with the disorder are inherited in an autosomal recessive pattern.

In some cases different mutations in the same gene result in different types of ED. An example is mutations in the *TP63* gene on the long arm of chromosome 3 at 3q28. Some types of ED that were initially thought to be distinct syndromes are now known to result from different mutations in the *TP63* gene. They include Rapp-Hodgkin syndrome, Hay-Wells syndrome, ankyloblepharon-ectodermal defects-cleft lip/palate (AEC) syndrome, and ectrodactyly-ectodermal dysplasia-cleft (EEC) syndrome.

Other EDs that are associated with identified genes include Clouston syndrome, caused by mutations in the *GJB6* gene on the long arm of chromosome 13 at 13q12 and inherited in an autosomal dominant pattern; Witkop syndrome, caused by mutations in the *MSX1* gene on the short arm of chromosome 4 at 4p16.2 and inherited in an autosomal dominant pattern; Naegeli-Franceschetti-Jadassohn syndrome (NFJS), caused by mutations in the *KRT14* gene on the long arm of chromosome 17 at 17q21.2 and inherited in an autosomal dominant pattern; oculodentodigital dysplasia, caused by mutations in the *GJA1* gene on the long arm of chromosome 6 at 6q22.31 and inherited in an autosomal dominant pattern, although some cases of this ED are *de novo* mutations; and focal dermal hypoplasia, caused by mutations in the *PORCN* gene on the short arm of the X chromosome at Xp11.23 and inherited in an X-linked dominant pattern. Focal dermal hypoplasia predominantly affects females because the genetic mutation is lethal to male fetuses.

Demographics

The exact incidence of EDs is not accurately known because there are so many different EDs, some of which have been reported in only a single family. The frequency of the different EDs in a given population is also highly variable; some, like Naegeli-Franceschetti-Jadassohn syndrome, are estimated to affect only 1 person in every 2 million. There are fewer than 1,000 cases of oculodentodigital dysplasia reported in the literature. In the United States, the prevalence of hypohidrotic ED, the most common variant, is estimated to be 1 case per 100,000 births. It is estimated that there are about 125,000 persons in the United States who are carriers of the mutations that cause the EDs.

Worldwide, the prevalence of ED is estimated at 7 cases per 10,000 births. Although the EDs can affect persons of all races and ethnic groups, some researchers think that fair-skinned Caucasians are at increased risk. Hidrotic ectodermal dysplasia appears to be more common in French Canadians than in other ethnic groups, and Witkop syndrome is associated with Mennonites of Dutch ancestry living in Canada.

Apart from the X-linked EDs, males and females are equally affected by these disorders.

Signs and symptoms

Most ED conditions cause significant dental abnormalities. In some cases, the majority of the primary (baby) and secondary (adult) teeth are missing. Teeth that are present may show a characteristic conical, pointed shape (pegteeth) or have abnormal enamel that is prone to cavities.

Hair is often thin with an abnormal texture. In hypohidrotic ED, the scalp hair is thin during childhood and ultimately shows premature balding. Although body hair, eyebrows, and eyelashes are also sparse in this condition, beard and mustache hair are normal. Hair is also sparse in EEC syndrome. In tricho-dento-osseous syndrome and Hay-Wells syndrome, the hair is sparse, coarse, and wiry. Individuals with incontinentia pigmenti may have patchy, bald areas of abnormal skin on the scalp. Frequent scalp infections occur in many of the ectodermal dysplasias.

A variety of skin abnormalities may occur in ED conditions. The skin may be dry, thin, and prone to eczema, infection, cracking, bleeding, and other problems. It may be marked by areas of uneven pigmentation, as in Naegeli-Franceschetti-Jadassohn syndrome, or by pinkish-yellow bumps on the skin, as in focal dermal hypoplasia. In hypohidrotic ED, sebaceous glands (the oil glands within the skin) are absent, causing severe dryness. Increased pigmentation may occur around the eyes (in hypohidrotic dysplasia), over the joints (in hidrotic ED), or in a linear pattern over the trunk (in incontinentia pigmenti). Hyperkeratosis, or thickened skin, occurs on the palms and soles of the feet in hidrotic ED (Clouston syndrome). Reddening and blistering of the skin may occur during infancy in incontinentia pigmenti. In Hay-Wells syndrome, abnormal bands of skin may occur between the upper and lower jaws and between the eyelids.

Decreased numbers of sweat glands and associated impaired sweating ability is an important feature of hypohidrotic ED. This characteristic can lead to life-threatening hyperthermia in hot environments or with physical exertion. Sweating is normal in most other ectodermal dysplasias.

Many EDs involve abnormalities of the mucous membranes. Production of tears and saliva may be deficient. In hypohidrotic ED, the mucous glands in the respiratory tract may be absent or decreased in number, leading to dryness, infections, and an unusual foul-smelling secretion associated with atrophy of the nasal tissues known as ozena. In some cases, dryness of the pharynx and larynx may affect the quality of the voice.

Fingernails and toenails are abnormal in many of the EDs. In EEC syndrome, the nails may be thin and brittle. Nails may be absent or abnormally formed in Hay-Wells syndrome, Rapp-Hodgkin syndrome, hidrotic ED, Witkop syndrome, and incontinentia pigmenti. Nails are normal, however, in hypohidrotic ED.

Some individuals with ED, particularly those with EEC syndrome, may have hearing impairment.

Structural birth defects may occur in some EDs. In EEC, Hay-Wells, and Rapp-Hodgkin syndromes, cleft lip and palate may occur. EEC is also characterized by split hand/split foot (or “lobster claw”) malformations and genitourinary anomalies. Amastia (absence of the breast) may occur in hypohidrotic ED, and breasts may be underdeveloped in incontinentia pigmenti and EEC syndrome. Some individuals with incontinentia pigmenti may have defects of the eye (such as congenitally crossed eyes, cataracts, or atrophy of the optic nerve) or central nervous system (such as a small head size, intellectual disability, or seizures). Cranioectodermal dysplasia is associated with deformities of the rib cage leading to breathing difficulties, as well as with disorders of the kidneys, liver, and heart.

Children with EDA-ID have defective immune systems that produce abnormally low levels of antibodies to fight off bacteria or viruses. They have frequent infections of the lungs (pneumonia), ears, skin, digestive tract, sinuses, and lymph nodes. About a quarter of these children also have chronic inflammatory conditions like rheumatoid arthritis.

Diagnosis

The diagnosis of an ED condition is typically based on clinical findings (physical examination, medical and family history), most often by a pediatrician or pediatric dermatologist. Although the EDs are congenital (present at birth), they may not be diagnosed until later infancy or early childhood, when the abnormalities in the teeth, hair, skin, and nails become apparent. With the exception of type I incontinentia pigmenti, there are no laboratory studies that are considered diagnostic. High-resolution chromosome study may be considered diagnostic for type I incontinentia pigmenti, as it can reveal the X chromosome rearrangements that appear to cause the condition.

KEY TERMS

Amastia—A birth defect involving the absence of mammary glands.

Anhidrosis—Complete inability to sweat in response to heat.

Congenital—Refers to a disorder that is present at birth.

De novo mutation—A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

Dysplasia—The abnormal growth or development of a tissue or organ.

Eccrine—Pertaining to the sweat glands located over most of the human body. Their water-based sweat is the primary mechanism of cooling in humans.

Ectoderm—The outermost of the three embryonic germ layers, which later gives rise to the nervous system, skin, hair, teeth, and nails.

Ectrodactyly—A birth defect involving a split or cleft appearance of the hands and/or feet, also referred to as a “lobster-claw” malformation.

Eczema—Inflammation of the skin with redness and other variable signs such as crusts, watery discharge, and itching.

Hyperthermia—Body temperature that is much higher than normal (above 98.6°F).

Hypohidrosis—Insufficient perspiration or absent perspiration that may be either general or localized to a specific area.

Mesoderm—The middle germ layer in the developing embryo, lying between the ectoderm and the endoderm. It gives rise to muscle, cartilage, bone, and the subcutaneous layer of the skin.

Ozena—Also called atrophic rhinitis, it is a condition in which the bony ridges and mucous membranes of the nose waste away (atrophy), resulting in a foul-smelling bacteria-infected discharge.

X-linked dominant inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male or female, passed from an affected female who has the gene on one of her X chromosomes.

X-linked recessive inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male, passed from a female who has the gene on one of her X chromosomes. She is referred to as an unaffected carrier.

The high degree of variability within and overlap between the different ED conditions can lead to difficulty identifying the specific syndrome. The presence or absence of nail and sweat gland involvement are important distinguishing features.

In hypohidrotic ED (HED), determining whether or not a female relative of an affected male also carries the *EDA* gene may be difficult. Many clinical tests based on sweat pore and dental analysis have been attempted, but they are considered unreliable. Linkage analysis by way of tracing the Xq12-13 gene locus through the family is considered to be the best way to determine carrier status. When linkage analysis is successful, it may also be used for prenatal diagnosis. Molecular diagnostic testing has made significant advances in recent years; tests are available for all the genes associated with the EDs included in this entry.

Treatment and management

Treatment of most ED syndromes requires a multi-specialty team, typically including a dermatologist (skin

specialist), dentist or oral surgeon, and ophthalmologist (eye specialist), as well as a pediatrician.

In hypohidrotic ED, males are at risk of hyperthermia and potential central nervous system damage or death. Hot environments and fevers must be avoided or managed with cooling methods, such as misting the skin with water or moving to a cool climate. Air conditioning in home, school, and work environments is considered essential. The dry nasal passages may be treated with moisturizing inhalers or other solutions. Various skin treatments may be used to prevent cracking, bleeding, and infection. Protection from exposure to direct sunlight is often necessary.

Early and extensive dental work is required in most ED conditions. In childhood, successive dentures may be used, while dental implants and bridges may be used in adults. Orthodontic treatment may also be necessary.

The abnormal hair associated with the EDs is primarily a cosmetic problem and may be managed with wigs.

In EEC, Rapp-Hodgkin syndrome, and Hay-Wells syndrome, clefting of the lip and palate requires surgical

QUESTIONS TO ASK YOUR DOCTOR

- A family member has just been diagnosed with ectodermal dysplasia. What are some of the symptoms of this disorder?
- What causes ectodermal dysplasia? Can it be prevented?
- What kinds of treatments will our family member need to deal with his ectodermal dysplasia?
- Is the condition considered to be a serious or life-threatening disorder?

correction, with treatment of any associated speech, dental, or hearing problems.

Hand and foot malformations in EEC may require orthopedic or plastic surgery and/or occupational therapy. The abnormal skin banding that may occur in the mouth and between the eyelids in Hay-Wells syndrome also requires surgical correction.

Most children with an ED require psychological counseling as they grow older in order to cope with social problems resulting from their appearance and their need for special accommodations and treatments. One European study reported in 2015 that adults with EDs suffer from higher levels of anxiety and lower quality of life than persons with other orofacial conditions.

Clinical trials

There are 36 clinical trials on EDs and related conditions being conducted in the United States as of 2021. Some are studies of investigational treatments for the EDs, one is a trial of a diagnostic method that involves imaging sweat glands in newborns, and one is a study of carriers of X-linked EDs.

Prognosis

Among males with hypohidrotic ED, unrecognized episodes of hyperthermia are a dangerous complication. The mortality rate during infancy and early childhood in affected undiagnosed males is 30% due to neurologic damage associated with hyperthermic episodes. If affected males are diagnosed and managed appropriately, a normal life expectancy and normal intelligence can be expected.

The tissue abnormalities and birth defects that occur in the EDs are usually not life threatening; however,

individuals with EDA-ID rarely survive childhood because of their susceptibility to frequent infections.

EDs typically do not cause intellectual disability, although a minority of cases of incontinentia pigmenti and EEC syndrome may involve cognitive impairment.

Ectrodactyly-ectodermal dysplasia-clefting syndrome

Definition

Ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome is one of more than 100 ectodermal dysplasia syndromes. EEC syndrome is characterized by deformities of the hands and feet (ectrodactyly); abnormalities of the skin, hair, and nails (ectodermal dysplasia); and cleft lip and/or cleft palate (clefting). Other symptoms include dental, eye, skin, and kidney abnormalities.

Description

Ectodermal dysplasias (ED) are a group of inherited disorders that result from problems in early development of the ectodermal layer in the embryo. Problems with the ectoderm cause the hair, teeth, nail, and glands to develop and function abnormally. EEC syndrome is characterized by deformities of the hands and feet (ectrodactyly) that are sometimes referred to as lobster-claw deformities; abnormalities of the skin, hair, and nails (ectodermal dysplasia); and cleft lip and/or cleft palate (clefting). Other abnormalities include absence of the teeth and other dental abnormalities, decreased ability to sweat, absence of tear ducts, photophobia (increased sensitivity to light), and kidney abnormalities. Most individuals with EEC syndrome have some of these abnormalities, but very few individuals have all of these abnormalities.

EEC syndrome is a genetic disorder with autosomal dominant inheritance with incomplete penetrance and variable expression. It can be inherited from a parent, but many individuals are the first in their family to be affected. DNA testing is now available and may be used to clarify the diagnosis in an individual with characteristic symptoms of the syndrome.

The cosmetic concerns of EEC can have a tremendous impact on the quality of life of an individual with EEC syndrome. The facial and limb differences can be socially isolating and physically challenging. Children and adults with EEC may be socially ostracized due to their physical appearance. Many individuals erroneously assume that people with EEC syndrome have limited abilities. It is important to increase awareness with educational programs and to take proactive steps to foster self-esteem in children with EEC syndrome.

Genetic profile

EEC syndrome has autosomal dominant inheritance with incomplete penetrance and variable expression. It is caused by mutations in the *p63* gene, which is located

Mother and child with ectrodactyly-ectodermal dysplasia-clefting syndrome. (Maria Platt-Evans/Science Source)

on the long arm of chromosome 3 (3q27). The *p63* gene appears to be necessary for the normal development of the skin and limbs.

Mutations in the *p63* gene are inherited in an autosomal dominant manner. Every individual has two *p63* genes: one from their father and one from their mother. In an autosomal dominant disorder, only one gene has to have a mutation for the person to have the EEC disorder. Some individuals with EEC syndrome are born to unaffected parents. Their EEC syndrome is the result of a *de novo*, or new, mutation. No one knows the cause of *de novo* mutations or why they occur so frequently in EEC syndrome. Because individuals pass half of their genes onto their children, a person with EEC syndrome has a 50% chance that their child will also inherit EEC syndrome. If two unaffected people have a child with EEC syndrome, they have about a 4% risk to have another child with EEC syndrome. This increased recurrence risk is due to the possibility of germ-line mosaicism. Germ-line mosaicism is the presence of two cell lines in the reproductive cells (eggs or sperm cells) of an individual. Thus, a parent of a child with EEC syndrome may have one normal cell line and one cell that contains the mutation for EEC syndrome.

While EEC syndrome has autosomal dominant inheritance, it also shows incomplete penetrance. “Incomplete penetrance” is the term that is used to describe individuals with a mutation in a gene who do not have any symptoms of a particular disease. Although this is very rare, there are some large families in which this phenomenon has been documented. Because the physical findings of EEC syndrome can be so variable, it is important to carefully examine other family members to make sure that they do not have an extremely mild case of EEC syndrome.

The findings or symptoms of EEC vary from family to family and even from person to person within the same family. For example, one sibling may have cleft lip and hand abnormalities, while another sibling may have kidney and eye abnormalities. This phenomenon is referred to as variable expression. Most ectodermal dysplasias show some degree of variable expression. This can often make it very difficult for a physician to make an exact diagnosis.

Demographics

The overall incidence of ectodermal dysplasias in the United States is 7 out of 10,000 people. Because the findings of EEC syndrome overlap those seen in other ectodermal dysplasias, the exact prevalence of EEC syndrome is not known. With the advent of DNA testing, it may soon be possible to get an accurate prevalence figure for EEC syndrome, but, as of 2021, this is not yet possible.

Signs and symptoms

In order to understand the signs and symptoms of EEC syndrome it is important to understand a little about early embryonic development. Very early in pregnancy, the cells that will develop into the embryo are organized as a small round ball. These cells eventually separate into three distinct layers: the endoderm, the mesoderm, and the ectoderm. The endoderm can be thought of as the inside layer. Cells from the endoderm will eventually form the lining of the digestive tract and the respiratory tract. The mesoderm can be thought of as the middle layer, and the cells of the mesoderm will eventually become the muscles, bones, cartilage, heart, and blood vessels. The ectoderm (involved in EEC syndrome) can be thought of as the outside layer. The cells of the ectoderm will eventually become the skin, hair, nails, brain, and nervous system. Any disruption of the development of the ectoderm will lead to disruption of the organs formed from this layer.

EEC syndrome is the result of a disruption of the ectoderm layer very early in development. This

disruption causes the specific defects seen in EEC syndrome, including defects of the skin, hair, nails, and other organs. The exact nature of this disruption or problem in formation of the ectoderm is not known. Research in this area is ongoing.

EEC syndrome is a disorder that causes multiple congenital abnormalities. Although these anomalies appear to be diverse, they all arise from the same underlying defect, or insult, to the early embryonic ectodermal tissue. Ectodermal tissue is responsible for the formation of the limbs, nails, eyes, skin, hair, teeth, kidneys, glands, and face. All of these organs and systems are affected to some degree in EEC syndrome. Most individuals will have some of the EEC abnormalities, but it is very rare for one individual to have all of these abnormalities.

Abnormalities of the hands and feet of individuals affected with EEC may include:

- ectrodactyly (lobster-claw deformity) of the hands and feet
- syndactyly (webbed fingers or toes)

Abnormalities of the eyes of affected individuals may include:

- nasolacrimal duct obstruction (tear duct obstruction)
- excessive lacrimation (tears)
- blepharophimosis/blepharospasm
- corneal ulcers and scarring
- telecanthus
- photophobia

Skin abnormalities of individuals affected with EEC may include:

- dry skin
- lack of sweat pores
- thin skin/generalized skin atrophy
- hyperkeratosis (thickened skin)

Individuals affected with EEC may have hair abnormalities, including:

- dry, brittle hair
- generalized depigmentation of hair
- fine hair
- sparse hair, or alopecia areata

Teeth abnormalities in affected individuals may include:

- abnormalities in the tooth buds, resulting in missing or abnormally shaped teeth
- defective enamel
- small teeth

Abnormalities of the kidneys of affected individuals may include:

- dilated ureters or ureteral atresia
- double ureters
- hydronephrosis
- multiple renal cysts
- renal agenesis
- renal dysplasia

Gland abnormalities of individuals affected with EEC may include:

- absent or hypoplastic thymus
- hypopituitarism
- isolated growth hormone deficiency
- pituitary diabetes insipidus

Facial abnormalities of affected individuals may include:

- cleft lip
- cleft palate
- malformed ears

Additionally, individuals affected with EEC can experience nail dystrophy.

There are two other ectodermal dysplasia syndromes that closely resemble EEC syndrome: Rapp-Hodgkin syndrome (RHS) and ankyloblepharon-ectodermal defects-cleft lip and palate (AEC) syndrome (also known as Hay-Wells syndrome). These syndromes share some of the specific findings of EEC syndrome, but differ in important ways.

Rapp-Hodgkin syndrome (RHS) is another type of ED associated with cleft lip and palate. However, RHS does not share the hand and foot defects of EEC syndrome. People with RHS do have some sweating problems, and their hair grows slowly and is coarse. Some affected individuals have persistent scalp dermatitis. As a rule, individuals with RHS have more teeth than those with EEC. General health, intelligence, and lifespan are within normal expectations.

Hay-Wells syndrome (HWS), also known as ankyloblepharon-ectodermal dysplasia-cleft lip and palate syndrome, is one of several syndromes that affect both the ectoderm and structures that do not derive from the ectoderm. The scalp hair is sparse and wiry, while the eyelashes are sparse or absent. The nails may be absent or malformed, and the teeth and sweat glands may also be affected. The feature that differentiates HWS from the other ectodermal dysplasias is the fusion of the upper and lower eyelids usually by narrow bands of tissue connecting the lids (ankyloblepharon). Patients may also have inflammatory dermatitis of the scalp.

Diagnosis

The diagnosis of EEC syndrome can be complex because of the overlap of symptoms with other ectodermal dysplasia syndromes. The diagnosis of EEC syndrome is usually made through a combination of clinical exam, x-rays, kidney imaging tests, skin biopsy, and DNA testing.

To make the diagnosis of EEC, a physician must evaluate which ectodermally derived structures are involved and look for physical features that do not develop from the ectoderm. By looking at the specific pattern of defects, it may be possible to make a correct diagnosis, but because of the overlap between other ectodermal dysplasias, it can often be difficult to make a definitive diagnosis based on the clinical exam alone. DNA testing and other tests can help aid in the diagnosis.

X-rays are often helpful in establishing the diagnosis of EEC syndrome. X-rays may be taken of the jaw to look for dental abnormalities, while x-rays of the limbs may be done to look for subtle abnormalities that may not be seen with a clinical exam. The presence of dental abnormalities or limb abnormalities would add to the suspicion that a person had EEC syndrome.

Because individuals with EEC syndrome can have kidney abnormalities, it is important to assess their kidney structure. This can be done using an IV pyelogram or ultrasound. The presence of a kidney abnormality would lend credence to the diagnosis of EEC syndrome, but the absence of a kidney abnormality does not rule out the diagnosis, as not every person with EEC syndrome has every symptom.

A skin biopsy involves removing a small amount of several layers of skin to examine them under a microscope. In EEC syndrome, the skin cells themselves may be abnormal. In addition, the sweat glands may be abnormal in number or shape.

DNA testing can also be performed on blood samples from children or adults. The presence of a mutation in the *p63* gene would confirm the diagnosis of EEC syndrome. Because scientists have not yet found all of the mutations in this gene, the absence of a detectable mutation does not completely rule out the diagnosis.

The diagnosis of EEC syndrome can also be made prenatally (during pregnancy) either by ultrasound (sonogram) or by prenatal DNA testing. Sonograms use sound waves to provide an image of a fetus. The structural abnormalities of EEC syndrome, including cleft lip, kidney abnormalities, and limb abnormalities, can be detected during the second trimester of pregnancy. Because of the overlap in some of the structural

KEY TERMS

Ectoderm—Embryonic cells that are affected in EEC syndrome.

Ectrodactyly—Lobster-claw deformities of the hands and feet and missing digits on the hands and feet.

Incomplete penetrance—Absence of disease in an individual known to carry the gene for that disease.

Variable expression—Ability of the same gene to cause different symptoms in different people (with the same disorder).

abnormalities of the ectodermal dysplasias, it can be very difficult to definitively diagnose EEC syndrome by sonogram. Other ectodermal dysplasias can look very similar to EEC syndrome on a sonogram. DNA testing can clarify ambiguous ultrasound findings.

Prenatal testing can also be done using DNA testing. A sample of tissue from a fetus is obtained by either chorionic villi sampling (CVS) or by amniocentesis. CVS is generally done between 10 and 12 weeks of pregnancy, and amniocentesis is done between 14 and 18 weeks of pregnancy. CVS involves removing a small amount of tissue from the developing placenta. The tissue in the placenta contains the same DNA as the fetus. Amniocentesis involves removing a small amount of fluid from around the fetus. This fluid contains some fetal skin cells. DNA can be isolated from these skin cells. The fetal DNA is then tested to determine if it contains mutations in the *p63* gene that causes EEC syndrome. Because not all of the mutations causing EEC syndrome have been found, DNA testing is not always definitive and the interpretation of the test results is best done by a genetics professional.

Treatment and management

There is no cure for EEC syndrome, but there are many treatments available to address the symptoms. These treatments include surgery, dental care, prevention of complications from hypohydrosis (abnormal sweating), and other preventive treatments.

Individuals with EEC syndrome may need surgery to correct cleft lips, cleft palates, and abnormalities with their hands and feet. Correction of cleft lip is usually done in infancy, as is surgery for cleft palate. Correction of cleft palate is important for feeding and for speech. Surgery may be done on hand and foot abnormalities to improve the function of these limbs, to improve the appearance of these limbs, and to aid in shoe fit.

QUESTIONS TO ASK YOUR DOCTOR

- How can I help my child with EEC build self-esteem?
- What are the most effective treatments for the symptoms of EEC?
- What sort of continuing health care will my child with EEC require?

Typically, patients with EEC syndrome will need extensive dental work. X-rays may be taken to document the presence or absence of teeth. Abnormal teeth may be pulled or capped. Replacement dentures may be worn during childhood. After growth has ended, many individuals receive dental implants.

Hypohydrosis, or impaired sweating, is a major complication of EEC syndrome. Without normal sweating, the body cannot regulate temperature properly. Therefore, overheating is a common problem and can lead to seizures, coma, and death in severe cases. It is important that affected individuals with an impaired ability to sweat follow the general precautions of using air conditioning when necessary, avoiding vigorous exercise, wearing light clothing, and avoiding hot temperatures.

Abnormal development of the eye can result in dryness of the eye, cataracts, and vision defects. Artificial tears can be used to protect the eyes from corneal scarring, which can lead to blindness if left untreated.

Prognosis

The prognosis for most individuals with EEC syndrome is very good. Life expectancy ranges from slightly reduced to normal. The most life-threatening complications come from sweating problems. Individuals with an impaired ability to sweat are at risk to overheat, which can lead to seizures, coma, and death. The life expectancy of individuals with EEC syndrome without sweating problems is expected to be normal.

The prognosis for most people with EEC syndrome is very good. In general, they have minimal and manageable serious medical problems, normal IQ, and most achieve success and have a long life, regardless of their disabilities. Successful social adaptation plays an important role in the ultimate success and happiness of an individual with EEC syndrome. It is very important that the career and life choices of an individual with EEC syndrome not be limited by preconceived ideas about their abilities.

Edwards syndrome

Definition

Edwards syndrome is a genetic syndrome of multiple congenital anomalies and severe-to-profound intellectual disability. It is caused by the presence of an extra chromosome 18 in some or all of the cells of the body. Babies with the condition usually do not survive past their first several months. Trisomy 18 in the embryo/fetus is also a common chromosomal cause of pregnancy loss.

Description

Chromosomes are the microscopic structures inside cells that carry the genes. The genetic material inside each cell contains all of the instructions the body needs to develop and function normally. Humans have 23 different pairs of chromosomes. Chromosomes 1–22 are numbered from largest to smallest and as a group are known as the autosomes. The last pair of chromosomes are designated X and Y and are known as the sex chromosomes—females have two X chromosomes, and males have one X and one Y. Other than sperm and eggs, each cell in the body normally has 46 chromosomes—a pair of each of the autosomes plus two sex chromosomes. In order for normal development and functioning to occur, chromosomes and genes must be present in the correct quantity and in the correct proportion to each other. Too much or too little genetic material usually causes serious problems.

The term “euploid” means “good set” and is used to designate a full set of 46 chromosomes. A cell is aneuploid (“not a good set”) if it has any number of chromosomes other than 46. A trisomy is one type of aneuploidy and refers to a cell that contains three of the same chromosome. Trisomy 18, then, refers to three chromosomes 18. After Down syndrome (trisomy 21), trisomy 18 is the most common autosomal aneuploid condition seen in live-born babies.

Edwards syndrome is made up of a specific but broad pattern of multiple congenital anomalies and intellectual disability. Babies with Edwards syndrome tend to have similar physical features and medical problems because they all have the same genetic imbalance—an extra copy of the genes on chromosome 18. The physical anomalies associated with Edwards syndrome involve nearly every organ and system of the body. However,

some anomalies occur more often than others, such as those of the heart, kidney, brain, skeleton, and craniofacial (head and face) area. The birth defects are typically serious and, combined with the large number of anomalies possible, result in a high mortality rate. About 60% of newborns with Edwards syndrome die within the first week, and 80% do not survive past the first month. Even those with Edwards syndrome who live longer will have severe to profound intellectual disability and chronic medical problems, necessitating involved care and monitoring throughout their lives.

Genetic profile

Edwards syndrome occurs in three different forms: full trisomy 18, mosaic trisomy 18, and partial trisomy 18. Before each of these is described, however, it is helpful to review the basics of normal reproduction and early embryonic development. As noted, cells in the body normally contain 46 chromosomes in 23 pairs, except sperm in males and eggs in females, which contain one chromosome of each pair, or 23 total. Meiosis is the process by which sperm and eggs, collectively known as gametes, are produced. In normal meiosis, the 46 chromosomes line up in pairs in the middle of a cell, and the cell divides down the middle separating each pair of chromosomes. When a sperm fertilizes an egg at conception, the 23 chromosomes from each gamete combine. A process of repeated chromosome duplication followed by cell division, known as mitosis, then begins. A cell that goes through mitosis produces two new cells, each with 46 chromosomes. A developing human is called an embryo during the eight weeks after conception, and a fetus for the remainder of pregnancy.

Full trisomy 18

Occasionally, chromosomes of a single pair do not separate during meiosis, an abnormal process known as nondisjunction. The result is one gamete with 24 chromosomes and another with 22. If a gamete with 24 chromosomes results in conception with a normal counterpart, an embryo with 47 chromosomes is produced. In most cases, all cells in the body will then have 47 chromosomes, a condition known as full trisomy 18 (when referring to an individual with the disorder, unless otherwise specified, the term “trisomy 18” implies a full trisomy, whereas Edwards syndrome may refer to any of the forms).

Nondisjunction of two chromosomes 18 during the formation of an egg or sperm is by far the most common cause of Edwards syndrome. Nondisjunction is a chance occurrence, with no known causative or preventive factors. The incidence of nondisjunction does increase, however, as men and women age. For anyone who has a fetus

or child diagnosed with trisomy 18, the risk for a chromosomal disorder of any type in subsequent offspring is about 1%, the exception being women over age 35, who face their age-related risk.

Mosaic trisomy 18

If the body contains a mixture of cells, some with trisomy 18 and some with a normal chromosome count, the condition is called mosaic trisomy 18. A small percentage of Edwards syndrome cases are due to mosaic trisomy 18.

Mosaic trisomy 18 occurs in one of two ways. The first involves mitotic (rather than meiotic) nondisjunction of chromosomes 18, in which a cell undergoing mitosis in a chromosomally normal embryo produces one cell with trisomy 18 and another with monosomy 18. The cell with monosomy 18 cannot survive, but if the trisomic cell survives, all cells in the body derived from it will have trisomy 18. These trisomic cells, combined with the normal cells that continue to develop, result in mosaic trisomy 18. The other cause of mosaicism involves an embryo with full trisomy 18. In this case, however, one cell loses its extra chromosome during mitosis. The result is a euploid cell, which in turn produces a euploid cell line in addition to the original trisomic cell line. Since mitotic nondisjunction appears to be the cause in most cases, and is due purely to chance, the recurrence risk for subsequent offspring after the diagnosis of mosaic trisomy 18 is less than 1%.

Because they have some normal cells, individuals with mosaic trisomy 18 tend to be less severely affected than those with full trisomy 18, but not always. Much of the prognosis depends on the total percentage of trisomic cells in the body and/or the proportion of trisomic cells in specific tissues and organs. There is no way to determine exact percentages of cells and, therefore, no way to provide an accurate prognosis.

Partial trisomy 18

A third cause of Edwards syndrome is a rearrangement, or translocation, of genetic material between chromosome 18 and another chromosome. An unbalanced chromosome translocation (extra and/or missing genetic material) may result in an embryo that has an extra piece of chromosome 18, known as partial trisomy 18. If cells are trisomic for a portion of chromosome 18, the result could be a form of Edwards syndrome. However, translocations between chromosomes can be complicated, and some cases of partial trisomy 18 may result in a pattern of anomalies that does not resemble Edwards syndrome.

Unbalanced translocations can occur in an embryo for the first time (*de novo*), or they can be inherited from

a healthy parent who is a carrier of the translocation in a balanced state (no missing or extra genetic material). Normal blood chromosome tests on both parents implies the translocation was *de novo*, which means no increased risk for subsequent offspring. Detection of a balanced translocation in one parent, however, presents an increased risk for unbalanced translocations in subsequent offspring, as well as an increased risk for pregnancy loss. In cases of partial trisomy 18, genetic counseling is critical to help determine risks and available options. Chromosome translocations resulting in partial trisomy 18 make up a small percentage of Edwards syndrome cases.

Demographics

The incidence of Edwards syndrome is about 1 in 5,000 births. Two-thirds of all newborns with the condition are female, probably because males with trisomy 18 are more likely to be miscarried. The condition is not known to occur more frequently in any ethnic group or in any part of the world. Increased parental age is the only factor known to result in a greater risk for trisomy 18. In the United States, parents of babies with trisomy 18 average about 32 years of age, while 26 is the average age for parents of children without a chromosomal disorder. The risk increases with age in both sexes, but begins earlier and is more pronounced in women.

Increasing maternal age elevates the risk for chromosomal disorders due to nondisjunction in general, not just trisomy 18. For instance, a 20-year-old woman has about a 1 in 10,000 chance of having a child with trisomy 18, while the risk of having a child with *any* chromosomal disorder at that age is 1 in 800. By age 35, those same risks have risen to 1 in 2,000 and 1 in 200, respectively, and increase to 1 in 600 and 1 in 65 at age 40. Other common chromosomal disorders caused by nondisjunction that result in live birth include trisomy 21 (Down syndrome), trisomy 13 (Patau syndrome), and several conditions caused by aneuploidy of the sex chromosomes.

Signs and symptoms

Many physical anomalies and medical complications are associated with Edwards syndrome. In fact, well over 100 different anomalies have been reported in the medical literature. The more common findings are categorized and described below.

Prenatal anomalies

The majority of pregnancies in which the embryo/fetus has trisomy 18 will result in miscarriage or stillbirth. Some physical anomalies of the heart, skeleton, brain, kidneys, and body walls have the best chance of being

detected by prenatal ultrasound. Other pregnancy-related findings include intrauterine growth restriction (IUGR) of the fetus, a single umbilical artery (also called two-vessel cord), and too much (polyhydramnios) or too little (oligohydramnios) amniotic fluid. While detection of fetal anomalies by ultrasound may lead to suspicion of Edwards syndrome, the diagnosis can only be confirmed by chromosome testing. Women carrying a fetus with Edwards syndrome sometimes report they feel little movement. Cesarean sections are more common due to abnormal fetal position or fetal distress near term.

General anomalies

Of those babies with Edwards syndrome that are live-born, two-thirds are delivered several weeks earlier or later than their expected due date. Low birth weight is common, as are low Apgar scores (measurements of a newborn's activity just after birth). Newborns are frail and tend to have a weak cry and difficulty feeding. Muscles may be poorly developed and often become tight and contracted (hypertonic). Extra hair (hirsutism) on the forehead and back is sometimes seen, as is loose, redundant skin.

Abnormalities of the lungs, kidneys, pancreas, spleen, and gastrointestinal system are associated with Edwards syndrome. The thyroid, thymus, and adrenal glands may be affected. Anomalies of the breastbone, radius (bone in the forearm), ribs, pelvis, and spine (scoliosis) are the more frequent skeletal findings. An abdominal wall defect (omphalocele) or hernia in the abdominal region may be present. Genital (sex organ) anomalies in both males and females have been described.

Heart anomalies

Ninety percent of babies with Edwards syndrome have one or more heart defects. Ventricular septal defects (VSD) and atrial septal defects (ASD), holes between the lower and upper chambers of the heart, respectively, are the most common cardiac problems. Patent ductus arteriosus (open connection between the pulmonary artery and aorta) and abnormal heart valves are also typical.

Craniofacial anomalies

Small head size (microcephaly) and a prominent occiput (back of the skull) are variations in skull shape typical of Edwards syndrome. Common facial features include widely spaced and/or slanted eyes, skin folds at the inner eyelid (epicanthal folds), ptosis (drooping) of the eyelids, low-set malformed ears, a small oral opening, narrow palate or cleft lip/palate, and a small jaw (micrognathia).

Hand and foot anomalies

A specific pattern of hand and foot anomalies is seen in most infants with Edwards syndrome. Clenched hands, with the index finger overlapping the third and the fifth finger overlapping the fourth, are a classic sign. Abnormal dermatoglyphics (fingerprint pattern), underdeveloped nails, outward or inward deviation of the hand, underdeveloped or absent thumbs, and a single crease across the palm are other frequent anomalies of the hands. Abnormalities affecting the feet include so-called “rocker-bottom feet” and clubfoot.

Central nervous system anomalies

Probably the most medically significant abnormal development that occurs in Edwards syndrome involves the brain. Some anomalies, such as a small cerebellum or hydrocephalus (increased fluid within the brain), can be visualized by ultrasound or other imaging techniques. However, some neurologic problems may only be noticed through their physical effects. For example, difficulties in feeding and breathing, hypertonic muscles, a diminished response to sound, seizures, and severe intellectual disability all indicate serious neurologic deficits. Spina bifida (open spine) is an infrequent but serious problem affecting the spinal cord. Babies with spina bifida usually have some degree of paralysis below the point on the back where the spine failed to close.

Diagnosis

Prenatal

Two screening and two diagnostic procedures for trisomy 18 are available to women during pregnancy. Following are brief explanations of each of the prenatal testing alternatives.

Maternal serum alpha-fetoprotein (MSAFP)-Plus, also known as the “triple screen,” is a routine maternal blood test offered to women at 15–20 weeks of pregnancy. It screens for open defects (such as spina bifida), Down syndrome, and trisomy 18. However, the screen’s sensitivity for trisomy 18 is not as well established as it is for the other conditions. Test results provide a risk adjustment only, not a diagnosis of any condition in the fetus. Any woman who has a result showing an increased risk for trisomy 18 in the fetus is offered follow-up testing such as amniocentesis or a detailed (level II) ultrasound.

Ultrasound, also called sonography, visualizes structures inside the body using high-frequency sound waves. During a prenatal ultrasound, a technician or doctor moves an instrument (transducer) back-and-forth across the skin of a pregnant woman’s lower abdomen. The transducer emits and receives harmless high-frequency

sound waves, which the ultrasound machine then converts into images of the fetus. Today’s sophisticated ultrasound machines, used by skilled technicians and doctors, can detect a number of different physical anomalies in the fetus. An ultrasound screen for trisomy 18 has good (but not absolute) sensitivity and presents no risk to the mother or fetus. Ultrasound becomes more sensitive for trisomy 18 the later in pregnancy it is performed. A level II ultrasound is performed after 20 weeks of pregnancy by a specialist (perinatologist). An abnormal ultrasound suggesting trisomy 18 would lead to the option of amniocentesis to confirm the diagnosis.

Chorionic villus sampling (CVS) is a method used to obtain tissue (chorionic villi) from the edge of the developing placenta. CVS is typically performed at 10–12 weeks of pregnancy. Chorionic villi come from the fetal side of the placenta and thus are chromosomally the same as cells in the fetus. Guided by ultrasound, a physician inserts a needle through either the abdomen or the cervix, into the placenta, and removes a small sample of tissue. Cells from the sample are analyzed under a microscope and a chromosome count is obtained. CVS carries a minimal risk for miscarriage and appears to have a very small risk of causing certain types of limb defects in the fetus as well. In about 3% of cases, CVS produces results that are difficult to interpret, which may lead to a follow-up amniocentesis.

Amniocentesis is the most widely used procedure to obtain fetal cells for genetic testing. The procedure can be performed any time after about 15 weeks of pregnancy. Under ultrasound guidance, a physician passes a thin needle through the lower abdomen into the amniotic sac and removes a small amount of amniotic fluid. Fetal skin cells that normally float in the fluid are then extracted for genetic analysis. Diagnosis of chromosomal disorders by this method is highly accurate. Amniocentesis causes a miscarriage in about 1 in 300 women who have the procedure, but poses no other serious risk to the fetus.

The benefit of CVS and amniocentesis is their accuracy at detecting trisomy 18, while the drawback is their risk to the pregnancy. The procedures are typically not offered unless the risk for a chromosomal disorder in the fetus is greater than the risk of the procedure, such as in pregnant women who are 35 or older, a couple with a previous child with trisomy 18, and any woman who carries, or whose partner carries, a balanced chromosome translocation. Detection of fetal anomalies by ultrasound or an abnormal MSAFP-Plus screen would lead to the option of amniocentesis.

The benefit of ultrasound and MSAFP-Plus is their lack of risk to the pregnancy, while the drawback is that

KEY TERMS

Aneuploidy—An abnormal number of chromosomes in a cell. Trisomy 18 and trisomy 13 are examples of aneuploid conditions.

Chromosome translocation—The exchange of genetic material between chromosomes, which can lead to extra or missing genetic material.

Geneticist—A specialist (MD or PhD) who has training and certification in diagnosing, managing, and counseling individuals/families with genetic disorders. Genetic counselors hold a master's degree in medical genetics and provide many of the same services as geneticists.

Meiosis—The process in which a cell in the testes or ovaries undergoes chromosome separation and cell division to produce sperm or eggs.

Mitosis—The process by which a somatic cell divides into two genetically identical cells in which the total number of chromosomes is maintained.

Mosaicism—A genetic condition resulting from a mutation, crossing over, or nondisjunction of chromosomes during cell division, causing a variation in the number of chromosomes in the cells.

Neonatologist—A physician (pediatrician) who has special training in the care of newborns (neonates).

Nondisjunction—Nonseparation of a chromosome pair, during either meiosis or mitosis.

Perinatologist—A physician (obstetrician) who has special training in managing difficult pregnancies. Some prenatal tests, such as chorionic villus sampling and level II ultrasound, are performed primarily by perinatologists.

Trisomy—The condition of having three identical chromosomes, instead of the normal two, in a cell.

neither procedure is diagnostic. Women who wish to first modify their risk for a fetal chromosomal disorder (and spina bifida) may choose screening. In any case, prenatal testing, whether screening or diagnostic, is never mandatory. Careful consideration must always be given to what action might be taken after an abnormal result and how reassuring a normal result might be.

Postnatal

A newborn with typical signs of Edwards syndrome can sometimes be diagnosed from a physical examination alone, especially by a physician who is familiar with the condition such as a geneticist or neonatologist. However, chromosome testing is the only method to confirm the

diagnosis and should always be performed if Edwards syndrome is suspected. Chromosome analysis helps to determine whether the underlying cause is full, mosaic, or partial trisomy 18 and may exclude other syndromes with similar signs and symptoms. Fetuses and newborns with Edwards syndrome sometimes die before chromosome analysis can be performed. In those cases, the diagnosis unfortunately cannot be confirmed, and an accurate cause and recurrence risk cannot be given.

Chromosome testing will detect full trisomy 18 with near-100% accuracy. Likewise, a translocation of chromosome 18 that produces signs of Edwards syndrome should be detected in virtually every case. Mosaic trisomy 18 presents more of a problem for chromosome analysis. The likelihood of confirming mosaic trisomy 18 depends on the percentage of trisomic cells in the particular tissue examined. Mosaicism, if present, can be confirmed by chromosome testing, and usually is. However, normal chromosome tests do not rule out the possibility of trisomic cells elsewhere in the body.

Treatment and management

Medical management of an infant with Edwards syndrome depends on the number and severity of anomalies present. In order to make the best-informed and most appropriate decisions for their child, parents must establish a close working relationship with the treating physicians.

Regardless of the medical procedures that might be performed, most babies with Edwards syndrome will not survive. Nearly all will be transferred to the neonatal intensive care unit (NICU) after birth. In some cases, parents elect not to have any life-prolonging heroic measures taken should their child experience cardiac or respiratory failure. They may also elect not to have certain types of surgery performed if other complicating medical problems make it unwise.

A more medically stable, less severely affected infant with Edwards syndrome will likely require various medical procedures and treatments. Surgical repair of certain physical anomalies, ventilator (breathing) support, medications, and/or placement of a feeding tube into the stomach are common. A baby may go home and remain there after some length of hospital stay, or may need to be readmitted one or more times. For those children that show some possibility of longer-term survival (more than six months), a plan for their medical care, both in the hospital and at home, must be established. Parents should also be informed of the various educational and support services available to them, including the Support Organization For Trisomy 18, 13, and Related Disorders (S.O.F.T.). Genetic counseling, to discuss the cause, prognosis, and

recurrence risks for their child's type of trisomy 18, can be of great help to parents.

There is no way to prevent the occurrence of trisomy 18. The technology now exists to test multiple embryos conceived by in vitro fertilization for certain chromosome anomalies, but this is very expensive and is only performed at several centers in the world.

Prognosis

The prognosis for a baby born with trisomy 18 is poor. On average, about 40% of newborns with trisomy 18 survive the first week, 20% are alive at one month, 6% at six months, and about 5% live past their first birthday. Survival rates are somewhat higher for children with mosaic or partial trisomy 18. As is the case before birth, males with trisomy 18 have a higher mortality rate than females, with about one-third as many males as females surviving infancy.

The outlook for trisomy 18 is not likely to change much in the coming years. Surgery to repair various birth defects has improved dramatically over the years. However, most babies with trisomy 18 do not die from repairable anomalies. For those parents whose babies are expected to survive some length of time, connecting them with support groups and providing them with accurate information as soon as possible is important.

Ehlers-Danlos syndrome

Definition

The Ehlers-Danlos syndromes (EDS) are a group of inherited disorders that affect collagen structure and function. Genetic abnormalities in the manufacturing of collagen within the body cause connective tissues to be abnormally weak.

Description

EDS was originally described by the Dutch physician Van Meekeren in 1682. Dr. Edvard Ehlers and Dr. Henri-Alexandre Danlos further characterized the disease in 1901 and 1908 respectively. EDS affects connective tissues of the body, such as skin, joints, and blood vessel walls. It is characterized by sagging skin, overly flexible joints, and weak tissue. These skin and joint abnormalities are caused by genetic mutations that lead to the production of a weakened form of a protein called collagen.

Collagen is a strong, fibrous protein that lends strength and elasticity to connective tissues such as the skin, tendons, organ walls, cartilage, and blood vessels. Each of these connective tissues requires collagen tailored to meet its specific purpose. The many variations in collagen are reflected in the number of genes dedicated to its production. There are at least 28 individual genes in humans that encode for more than 19 different types of collagen. Mutations in these genes can affect basic construction as well as the fine-tuned processing of the collagen.

There are 13 types or classifications of EDS. These classifications are based on the genetic transmission of each type. The characteristics of each type are described in detail at <https://rarediseases.org/rare-diseases/ehlers>

-danlos-syndrome. The types of Ehlers-Danlos syndrome are as follows:

- **Classical type:** Characterized by significantly lax joints, loose skin that bruises and tears easily, joint dislocations, and scoliosis (curvature of the spine).
- **Classical-like type:** Symptoms are similar to classical type, but the mutations and inheritance pattern differs from classical type.
- **Cardiac-valvular type:** A rare type with few classical symptoms but major damage to the aorta (the large blood vessel exiting the heart) that requires surgical correction.
- **Vascular type:** Characterized by loose skin, veins that are more visible than usual, ruptured arteries and bowels, club foot and hip deformities. This type may be fatal.
- **Hypermobility type:** Characterized by joint hypermobility and frequent joint dislocations. Degenerative joint diseases are common.
- **Arthrochalasia type:** Characterized by short stature, severely loose joints, joint dislocations, and in some cases, affected skin.
- **Dermatosparaxis type:** Characterized by extremely fragile skin that is very soft with excessive sagging and folding.

- **Kyphoscoliosis type:** Characterized by fragile globe of the eyes, significant skin and joint laxity, and severe scoliosis.
- **Brittle cornea syndrome:** A variant that affects the cornea of the eye.
- **Spondylodysplastic type:** A variant that affects primarily the spine and hands and can result in short stature and stunted growth.
- **Musculocontractural type:** Characterized by muscle weakness, developmental delays, and progressive multi-symptom complications.
- **Myopathic type:** Characterized by muscle weakness and muscles that do not function properly. Hearing loss and scoliosis may also be present. This variant shares many characteristics with the kyphoscoliosis type.
- **Periodontal type:** Affects the tissues around the teeth and gums and can result in premature tooth loss.

Genetic profile

There are numerous types of EDS, all caused by changes in one of several genes. Identified mutations occur in the *ADAMTS2*, *CHST14*, *COL1A1*, *COL1A2*,

A patient whose skin is very elastic due to the breakdown in collagen levels, a side effect of Ehlers-Danlos syndrome.

COL3A1, *COL5A1*, *COL5A2*, *COL3A1*, *NF469*, *PLOD1*, *SLC39A13*, and *ZNF469* genes, which are all involved in the collagen-production pathway. Mutations that cause the different forms of EDS disrupt the structure, production, or processing of collagen, which results in the weakening of connective tissues. Although a great deal of information is known regarding the changes in genes that cause EDS and their various inheritance patterns, gene mutations for all types of EDS have not been completely identified.

The manner in which EDS is inherited depends on the specific gene involved. There are two patterns of inheritance for EDS: autosomal dominant and autosomal recessive. Chromosomes are made up of hundreds of small units (genes), which contain the genetic material necessary for an individual to develop and function. Humans have 46 chromosomes, which are matched into 23 pairs. Because chromosomes are inherited in pairs, each individual receives two copies of each chromosome and likewise two copies of each gene, except for the gene that determines biological sex, in which the two genes can be the same (XX) or different (XY).

Changes or mutations in genes can cause genetic diseases in several different ways, many of which are represented within the spectrum of EDS. In autosomal dominant EDS, only one copy of a specific gene must be changed for a person to have EDS, and there is a 50% chance that any child of this person will have the disorder. Classical, vascular, hypermobility, arthrochalasia, myopathic, and periodontal types are inherited in the autosomal dominant pattern.

In an autosomal recessive inheritance pattern, both copies of a specific gene must be changed for a person to have EDS. If only one copy of an autosomal recessive EDS gene is changed, the person is referred to as a

carrier, meaning that he or she does not have any of the signs or symptoms of the disease itself but carries the possibility of passing on the changed gene to a future child. In the autosomal recessive pattern, a child of a carrier has a 25% chance of having the disorder and a 50% chance of being a carrier. Classical-like, cardiac valvular, dermatosparaxis, kyphoscoliotic, brittle cornea syndrome, spondylodysplastic, and musculocontractural types are inherited in an autosomal recessive pattern.

Demographics

According to the Ehlers-Danlos National Foundation, one in 3,500–5,000 people is affected by some form of EDS.

Signs and symptoms

Classical type

The major symptoms involved in EDS classical type affect the skin and joints. The skin has a smooth, velvety texture and bruises easily. Affected individuals typically have extensive scarring, particularly at the knees, elbows, forehead, and chin. The joints are hyperextensible, so there is a tendency toward dislocation of the hip, shoulder, elbow, knee, or clavicle. Due to decreased muscle tone, affected infants may experience a delay in reaching motor milestones. Children may have a tendency to develop hernias or other organ shifts within the abdomen. Sprains and partial or complete joint dislocations are also common. Symptoms can range from mild to severe. EDS classical type is inherited in an autosomal dominant manner.

There are three major clinical diagnostic criteria for EDS classical type: skin hyperextensibility, unusually wide scars, and joint hypermobility. At this time, there is no definitive test for the diagnosis of classical EDS. Both DNA and biochemical studies have been used to help identify affected individuals. In some cases, a skin biopsy has been found to be useful in confirming a diagnosis. Unfortunately, these tests are not sensitive enough to identify all individuals with classical EDS. If there are multiple affected individuals in a family, it may be possible to perform prenatal diagnosis using a DNA information technique known as a linkage study.

Hypermobility type

Excessively loose joints are the hallmark of this EDS type, formerly known as EDS type III. Both large joints, such as the elbows and knees, and small joints, such as toes and fingers, are affected. Partial and total joint dislocations are common and particularly involve the jaw, knee, and shoulder. Many individuals experience chronic limb and joint pain, although x-rays of these joints appear

normal. The skin may also bruise easily. Osteoarthritis is a common occurrence in adults. EDS hypermobility type is inherited in an autosomal dominant manner.

There are two major clinical diagnostic criteria for EDS hypermobility type: skin involvement (either hyperextensible skin or smooth and velvety skin) and generalized joint hypermobility. At this time, there is no test for this form of EDS.

Vascular type

Formerly called EDS type IV, EDS vascular type is the most severe form. The connective tissue in the intestines, arteries, uterus, and other hollow organs may be unusually weak, leading to organ or blood vessel rupture. Such ruptures are most likely to occur between ages 20 and 40, although they can occur any time and may be life-threatening.

There is a classic facial appearance associated with EDS vascular type. Affected individuals tend to have large eyes; a thin, pinched nose; thin lips; and a slim body. The skin is thin and translucent with veins dramatically visible, particularly across the chest.

The large joints have normal stability, but small joints in the hands and feet are loose and hyperextensible. The skin bruises easily. Other complications may include collapsed lungs, premature aging of the skin on the hands and feet, and ruptured arteries and veins. After surgery, there may be poor wound healing, a complication that tends to be frequent and severe. Pregnancy also carries the risk of complications. During and after pregnancy, there is an increased risk of the uterus rupturing and of arterial bleeding. Due to the severe complications associated with vascular type EDS, death usually occurs before age 50. A study of 419 individuals with EDS vascular type completed in 2000 found that the median survival rate was 48 years, with a range of 6–73 years.

There are four major clinical diagnostic criteria for EDS vascular type: thin translucent skin, arterial/intestinal/uterine fragility or rupture, extensive bruising, and characteristic facial appearance. EDS vascular type is caused by a change in the gene *COL3A1*, which codes for one of the collagen chains used to build collagen type III. Laboratory testing is available for this form of EDS. A skin biopsy may be used to demonstrate the structurally abnormal collagen. This type of biochemical test identifies more than 95% of individuals with EDS vascular type. Laboratory testing is recommended for individuals with two or more of the major criteria.

DNA analysis may also be used to identify the change within the *COL3A1* gene. This information may

be helpful for genetic counseling purposes. Prenatal testing is available for pregnancies in which an affected parent has been identified, and the DNA mutation is known or their biochemical abnormality has been demonstrated.

Kyphoscoliosis type

The major symptom of kyphoscoliosis type, formerly called EDS type VI, is general joint looseness. At birth, muscle tone is poor, and motor skill development is subsequently delayed. Infants with this type of EDS have an abnormal curvature of the spine (scoliosis), which becomes progressively worse with age, with affected individuals usually unable to walk by age 20. The eyes and skin are fragile and easily damaged, and blood vessel involvement is a possibility. The bones may also be affected as demonstrated by a decrease in bone mass. Kyphoscoliosis type is inherited in an autosomal recessive manner.

There are four major clinical diagnostic criteria for EDS kyphoscoliosis type: generally loose joints, low muscle tone at birth, scoliosis at birth (which worsens with age), and fragility of the eyes, which may give the white area of the eye a blue tint or cause the eye to rupture. This form of EDS is caused by a change in the *PLOD* gene on chromosome 1, which encodes the enzyme lysyl hydroxylase. A laboratory test is available in which urinary hydroxylysyl pyridinoline is measured. This urine test is extremely sensitive and specific for EDS kyphoscoliosis type. Laboratory testing is recommended for infants with three or more of the major diagnostic criteria.

Prenatal testing is available if a pregnancy is known to be at risk, and an identified affected family member has had positive laboratory testing. An amniocentesis may be performed, in which fetal cells are removed from the amniotic fluid, and enzyme activity is measured.

Arthrochalasia type

Dislocation of the hip joint typically accompanies arthrochalasia type EDS, formerly called EDS type VIIB. Other joints are also unusually loose, leading to recurrent partial and total dislocations. The skin has a high degree of stretchability and bruises easily. Individuals with this type of EDS may also experience mildly diminished bone mass, scoliosis, and poor muscle tone. Arthrochalasia type is inherited in an autosomal dominant manner.

There are two major clinical diagnostic criteria for EDS arthrochalasia type: severe generalized joint hypermobility and bilateral hip dislocation present at birth. This form of EDS is caused by a change in either of two components of collagen type I, called pro α 1(I) type A and

KEY TERMS

Arthrochalasia—Excessive looseness of the joints.

Blood vessels—General term for arteries, veins, and capillaries that transport blood throughout the body.

Cartilage—A tough, elastic tissue that is a building block for bone.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Connective tissue—A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

Dermatosparaxis—Skin fragility caused by abnormal collagen.

Hernia—A rupture in the wall of a body cavity, through which an organ may protrude.

Homeopathy—A holistic and natural approach to health care.

Hyperextensibility—The ability to extend a joint beyond the normal range.

Hypermobility—Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

Joint dislocation—The displacement of a bone from its socket or normal position.

Kyphoscoliosis—Abnormal front-to-back and side-to-side curvature of the spine.

Ligament—A type of connective tissue that connects bones or cartilage and provides support and strength to joints.

Osteoarthritis—A group of diseases and mechanical abnormalities involving degradation of joints.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than 10 degrees to the right or left as the doctor faces the patient.

Tendon—A strong connective tissue that connects muscle to bone.

Uterus—A muscular, hollow organ of the female reproductive tract. The uterus contains and nourishes the embryo and fetus from the time the fertilized egg is implanted until birth.

Vascular—Pertaining to blood vessels.

proa2(I) type B. A skin biopsy may be performed to demonstrate an abnormality in either component. Direct DNA testing is also available.

Dermatosparaxis type

Individuals with this type of EDS, once called type VIIC, have extremely fragile skin that bruises easily but does not scar excessively. The skin is soft and may sag, leading to an aged appearance even in young adults. Individuals may also experience hernias. Dermatosparaxis type is inherited in an autosomal recessive manner.

There are two major clinical diagnostic criteria for EDS dermatosparaxis type. These include severe skin fragility and sagging or aged-appearing skin. This form of EDS is caused by a change in the enzyme called procollagen I N-terminal peptidase. A skin biopsy may be performed for a definitive diagnosis of dermatosparaxis type.

Other types

Other types of EDS are less common and have not been as clearly defined as the aforementioned types. Forms of EDS within this category may present with soft, mildly stretchable skin, shortened bones, chronic diarrhea, joint hypermobility and dislocation, bladder rupture, or poor wound healing. Inheritance patterns within this group include X-linked recessive, autosomal dominant, and autosomal recessive.

Diagnosis

Clinical symptoms such as extreme joint looseness and unusual skin qualities, along with family history, can lead to a diagnosis of EDS. Specific tests, such as skin biopsies, are available for diagnosis of certain types of EDS, including vascular, arthrochalasia, and dermatosparaxis types. A skin biopsy involves removing a small sample of skin and examining its microscopic structure. A urine test is available for the kyphoscoliosis type.

Management of all types of EDS may include genetic counseling to help affected individuals and their families understand the disorder and its impact on other family members and future children.

If a couple has had a child diagnosed with EDS, the chance that they will have another child with the same disorder depends on what form of EDS the child has been diagnosed with and whether either parent is affected by the same disease.

Individuals diagnosed with an autosomal dominant form of EDS have a 50% chance of passing the same disorder on to a child in each pregnancy. Individuals diagnosed with an autosomal recessive form of EDS have a 25% chance of having a child with the disorder.

Prenatal diagnosis is available for specific forms of EDS, including kyphoscoliosis type and vascular type. However, prenatal testing is only a possibility in these types if the underlying defect has been found in another family member.

QUESTIONS TO ASK YOUR DOCTOR

- What is collagen and what functions does it have in the body?
- What is the pattern of inheritance of the various types of Ehlers-Danlos syndrome?
- What medications and other procedures are available for the treatment of my son's Ehlers-Danlos syndrome?
- What kind of future can my son expect to have as a result of inheriting this disorder?

Treatment and management

Medical therapy relies on managing symptoms and trying to prevent further complications. There is no cure for EDS.

Braces may be prescribed to stabilize joints, although surgery is sometimes necessary to repair joint damage caused by repeated dislocations. Physical therapy teaches individuals how to strengthen muscles around joints and may help to prevent or limit damage. Elective surgery is discouraged due to the high possibility of complications.

Alternative treatment

There are anecdotal reports that large daily doses (1–4 g) of vitamin C may help decrease bruising and aid in wound healing. Constitutional homeopathic treatment may be helpful in maintaining optimal health in persons with a diagnosis of EDS. Individuals with EDS should discuss these types of therapies with their doctor before beginning them on their own. Therapy that does not require medical consultation involves protecting the skin with sunscreen and avoiding activities that place stress on the joints.

Prognosis

The outlook for individuals with EDS depends on the type of EDS they have. Symptoms vary in severity, even within one subtype, and the frequency of complications changes on an individual basis. Some individuals have negligible symptoms, while others are severely restricted in their daily life. Extreme joint instability and scoliosis may limit a person's mobility. Most individuals will have a normal lifespan. However, those with blood vessel involvement, particularly those with EDS vascular type, have an increased risk of fatal complications.

EDS is a lifelong condition. Affected individuals may face social obstacles related to their disease on a daily basis. Some people with EDS have reported living with fears of significant and painful skin ruptures, of becoming pregnant (especially those with EDS vascular type), of their condition worsening, of becoming unemployed due to physical and emotional burdens, and of social stigmatization in general.

Clinical trials for EDS, including experimental drug treatments and procedures, are underway. Participation in a U.S. clinical trial is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>

Constant bruises, skin wounds, and trips to the hospital take their toll on both affected children and their parents. Prior to diagnosis, parents of children with EDS have found themselves under suspicion of child abuse.

Some people with EDS are not diagnosed until well into adulthood and, in the case of EDS vascular type, occasionally not until after death due to complications of the disorder. Not only may the diagnosis itself be devastating to the family, but in many cases other family members find out for the first time that they are at risk for being affected.

Although individuals with EDS face significant challenges, it is important to remember that each person is unique with his or her own distinguished qualities and potential. Persons with EDS can go on to have families and careers and become accomplished citizens, surmounting the challenges of their disease.

Ellis-van Creveld syndrome

Definition

Ellis-van Creveld syndrome is an individually recognized genetic condition characterized by short stature and malformations of the heart, limbs, nails, and teeth. The name given to this condition originates from Richard W. B. Ellis of Scotland and Simon van Creveld of the Netherlands. Each had a patient with this syndrome in his care when the two met by chance in an English train car on the way to a pediatric conference in the late 1930s.

Description

Ellis-van Creveld (EvC) syndrome primarily affects the skeletal system but is also associated with congenital heart defects. EvC syndrome is one of the six short rib polydactyly syndromes, or SRPS. There is considerable overlap between the features of these six syndromes. Clinical, radiological, and pathological studies are being conducted to determine if there are indeed six distinct SRPS, or if each is a different mutation at the gene that also causes Ellis-van Creveld syndrome.

Ellis-van Creveld syndrome is alternatively known as chondroectodermal dysplasia or mesoectodermal dysplasia. The name “chondroectodermal dysplasia” is meant to indicate a dysplasia, or abnormal growth or development, of the skeleton (chondro-) and the skin (ectodermal). The name “mesoectodermal dysplasia” is meant to indicate an abnormal growth or development of the skin (ectodermal) and primarily the middle portion of the bone (meso-). However, neither term defines the syndrome completely, and Ellis-van Creveld syndrome remains the most used name for both medical and common purposes.

Ellis-van Creveld syndrome is characterized by short arms and legs; short ribs; short fingers; polydactyly, or extra fingers or toes; and dysplastic, or abnormal, teeth and nails. Limb shortening is more noticeable in the legs than in the arms. Many older children affected by EvC syndrome develop knock knee, or genu valgum, which may have to be corrected by orthopedic surgery. The underdeveloped ribs generally cause a condition known as pectus carinatum, in which the chest is narrow and elongated. A sixth finger on both hands occurs in all patients with EvC syndrome, while extra toes are observed in approximately 20% of the EvC syndrome population. Polydactyly in affected individuals is always symmetric. That is, if the left hand possesses a sixth finger, the right hand will also possess a sixth finger.

Dysplastic, or abnormal, teeth and nails are observed in all individuals with EvC syndrome. The most common dental anomalies are teeth present at birth; wide spaces between permanent teeth; the late eruption of or the complete lack of some permanent teeth; and permanent teeth that more closely resemble baby teeth than permanent teeth. The most common nail abnormalities are absent or malformed fingernails or toenails. Thin, brittle hair is also observed in a majority of patients with EvC syndrome.

Congenital heart defects occur in approximately 50%–60% of affected individuals. The most common cardiac abnormality observed is a common atrium rather than the normal two-chambered atrium. This “hole in the heart” can often be surgically repaired, resulting in normal heart function.

Genetic profile

Ellis-van Creveld syndrome is an autosomal, or non-sex-linked, recessive condition. The gene responsible for EvC syndrome has been identified and its locus determined on the distal short arm of chromosome 4p. In 2000, it was shown that the *EvC* gene is the same gene that causes Weyers acrofacial dysostosis.

Certain mutations in the *EvC* gene cause EvC syndrome. In order for EvC syndrome to appear, the affected

KEY TERMS

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Dysplasia—The abnormal growth or development of a tissue or organ.

Heterozygous—Having two different versions of the same gene.

Homozygous—Having two identical copies of a gene.

Postaxial polydactyly—A condition in which an extra finger or toe is present outside the normal fifth digit.

Primary atrial septation—An improper division of the atria of the heart, or a “hole in the heart,” which results in the formation of a common atrium rather than the normal two-chambered atrium.

Short rib polydactyly syndromes—A collection of genetic disorders characterized by abnormally short ribs and extra fingers or toes. Research is ongoing to determine whether these disorders are the result of mutations in a common gene.

Weyers acrofacial dysostosis—A condition resulting from a mutation of the same gene that shows mutation in Ellis-van Creveld syndrome. As is usually the case when comparing expressions of the same gene mutation, the single-dose Weyers acrofacial dysostosis presents milder symptoms than the double-dose Ellis-van Creveld syndrome.

child must inherit a mutation of this gene from each parent. The child must receive two abnormal genes.

When the child receives only a single copy of an abnormal gene that would cause EvC syndrome, that child is affected with Weyers acrofacial dysostosis. Weyers acrofacial dysostosis is an autosomal dominant condition characterized by tooth and nail abnormalities, extra fingers and toes, and milder limb anomalies than those observed in Ellis-van Creveld syndrome. As is often the case in homozygous disorders, EvC syndrome presents much more pronounced physically observable and potentially life-threatening signs than the corresponding heterozygous condition, Weyers acrofacial dysostosis.

Demographics

Ellis-van Creveld syndrome has an incidence of approximately 1 in 60,000 to 200,000 live births. Ellis-

van Creveld syndrome has a much higher occurrence among the Old Order Amish, an isolated and inbred religious community in Lancaster County, Pennsylvania.

As a homozygous condition, both parents of an affected child must carry the abnormal *EvC* gene. The parents of a child with EvC syndrome have a one in four chance of having additional children affected with EvC syndrome. The transmission of such homozygous genetic disorders is facilitated by the close association among potentially related individuals in a relatively small and isolated population such as that of the Amish. Also, a relatively high frequency of EvC syndrome has been observed in the Aboriginal people of Western Australia. This high frequency has been attributed to a founder effect from Dutch castaways and genetic drift caused by the isolation and interbreeding of these peoples.

Signs and symptoms

Ellis-van Creveld syndrome is characterized by short limbs and short body length identifiable at birth. The average adult height range for those affected by EvC syndrome is 43–60 in. (109–152 cm). The head and neck are generally unaffected other than possible abnormalities of the upper lip, and dental anomalies including delayed eruption of the permanent teeth, which are generally underdeveloped and more similar to a child's teeth than to those of an adult. EvC syndrome is further characterized by congenital heart defects, usually a single upper chamber (atrium) rather than the normal two upper chambers. Affected individuals have short, poorly developed ribs, which leads to a narrow chest; this is termed “pectus carinatum.”

Males affected by EvC syndrome may present abnormalities of the penis in which the urethral opening occurs on the underside of the penis rather than at the tip of the glans (hypospadias); they may also have one or both testicles undescended (cryptorchidism). Further skeletal anomalies associated with EvC syndrome include low hips; a spur-like projection at the acetabula, the socket in the hipbone that accepts the head of the thighbone; a fusion of the capitate and hamate bones; two carpal bones, the fusion of which makes the formation of a fist difficult or impossible; knock-knee; clubfeet that turn down and in; and postaxial polydactyly, or extra fingers/toes that arise outside the normal fifth digit. Fingernails and toenails are generally malformed. Neurologically, mental retardation has been observed in patients with EvC syndrome, but it is not the norm. A brain abnormality of one of the normal cavities of the brain (Dandy-Walker syndrome) is also occasionally associated with EvC syndrome.

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “chondroectodermal dysplasia” mean?
- What kinds of treatments are available for dealing with the physical problems associated with my child’s medical disorder?
- What is my child’s prognosis, and what factors might affect that prognosis with age?
- Can you suggest support groups or other organizations for parents of children with Ellis-van Creveld syndrome?

Diagnosis

Ultrasound imaging of developing fetuses can reveal the limb shortening and underdeveloped ribs that are characteristic of the short rib polydactyly syndromes (SRPS), which includes Ellis-van Creveld syndrome. An ultrasound scan is now available after the 16th week of gestation that may identify extra digits in the developing fetus.

Ellis-van Creveld syndrome is generally differentially diagnosed from the other SRPS by the additional presence of atrial abnormalities. However, it is often difficult to distinguish EvC syndrome from two other forms of skeletal dysplasia. These are asphyxiating thoracic dysplasia (ATD), also known as Jeune syndrome; and short rib polydactyly syndrome (SRPS) type III, or Verma-Naumoff type SRPS. Individuals with Jeune syndrome often die of respiratory distress shortly after birth, whereas individuals diagnosed with EvC syndrome are more likely to die from congenital heart failure. Individuals with Jeune syndrome often have extra fingers or toes; but, unlike those with EvC syndrome, this polydactyly is often not symmetric. Individuals with Jeune syndrome do not show the nail and hair abnormalities observed in EvC syndrome. Older children can often be differentially diagnosed with Jeune syndrome rather than EvC syndrome if they develop kidney problems, which may also later lead to kidney failure as adults. Kidney dysfunction is not associated with EvC syndrome.

Verma-Naumoff type SRPS is virtually indistinguishable from EvC syndrome prior to birth. However, individuals with Verma-Naumoff type SRPS also exhibit heart, kidney, and intestinal malformations that are not present in the Ellis-van Creveld population. Verma-Naumoff type SRPS has an essentially 100% mortality rate within hours of birth, as those affected die

from respiratory distress. All three of these conditions arise from autosomal recessive inheritance. The genetic evidence is beginning to further the hypothesis that these three conditions are the result of mutations of the same gene on chromosome 4p that has been identified as the cause of EvC syndrome.

Treatment and management

Genetic counseling of individuals affected with either EvC syndrome or the allelic disorder, Weyers acrofacial dysostosis, may prevent the conception of EvC syndrome-affected children. Congenital heart defects associated with EvC syndrome may be surgically corrected. The potential outcome of such a procedure is normal heart function. Extra fingers or toes (polydactyly) can be surgically removed shortly after birth. This is more a cosmetic treatment than a necessary one in the case of fully developed extra digits. If a person affected with EvC syndrome develops genu valgum (knock knee), he or she may require orthopedic surgery to straighten the legs at the knee. Dental treatment also has an important role in management of EvC syndrome.

Many people of extremely short stature adapt their surroundings to their size. Others choose to undergo one of the bone lengthening procedures that have increasingly become available. These bone lengthening procedures are generally performed only on the limbs. They often do not offer complete relief to the EvC syndrome patient who may also have a smaller than normal thoracic cavity caused by undersized ribs.

Prognosis

Ellis-van Creveld syndrome is generally nonlethal, with approximately two-thirds of those affected surviving to adulthood. Mortality is higher when the congenital heart defects associated with EvC syndrome are also present. Approximately half of those affected with EvC syndrome with heart abnormalities die in childhood due to cardiorespiratory problems associated with these congenital heart defects or associated with pressure on the chest, primarily the lungs, caused by an underdeveloped rib cage. Of these, approximately one-half die within the first six months of life.

Emery-Dreifuss muscular dystrophy

Definition

Emery-Dreifuss muscular dystrophy (EDMD) is a rare childhood-onset degenerative muscle disease seen primarily in males. Emery-Dreifuss muscular dystrophy is characterized by a classic triad of symptoms. These include early-onset contractures, very slow progressive muscle weakness and degeneration involving the upper arms and lower legs, and cardiac (heart) muscle disease.

Description

EDMD is named for the doctors who first described it in the 1960s, Alan Emery and Fritz Dreifuss. EDMD affects the arms, legs, spine, face, neck, and heart. This disease is characterized by contractures of the elbows and the Achilles tendons at an early age, slowly progressive muscle wasting and weakness, and potentially life-threatening heart muscle disease. Intelligence is normal; however, physical problems may be severe.

Symptoms and disease severity may vary between individuals. Three modes of inheritance exist: X-linked, autosomal dominant, and autosomal recessive.

The symptoms of the autosomal dominant and X-linked forms of the disease are identical; however, the autosomal dominant form appears to have a later onset of symptoms.

Genetic profile

EDMD is caused by mutations in the *EMD* and *LMNA* genes. Both of these genes provide instructions for making proteins that are important in creating the nuclear envelope within cells. The nuclear envelope is the membrane that surrounds the nucleus in cells and is responsible for controlling what enters and exits the nucleus.

EDMD is inherited in different ways depending on which genetic mutation is responsible for the condition. Most commonly EDMD is inherited in an X-linked recessive manner and is caused by mutations in the *EMD* gene.

Less commonly, EDMD is inherited in an autosomal dominant pattern, meaning that only one copy of the mutated gene is necessary for the condition to be present. In these cases, EDMD is caused by mutations in the *LMNA* gene. Over 75% of these cases are caused by new mutations in the *LMNA* gene, and the individual has no other family members with the disease. The remaining EDMD cases caused by *LMNA* mutations involve families in which an abnormal *LMNA* is present.

EDMD is usually inherited in an X-linked recessive manner and is caused by mutations in the *EDM* gene. It is the third most common type of X-linked muscular dystrophy. Symptoms begin in the first decade of life. A tendency to walk on the toes is often one of the first signs of EDMD. Muscle weakness first affects the lower extremities usually at age four or five. X-linked diseases map to the human X chromosome, a sex chromosome. Females have two X chromosomes, whereas males have one X chromosome and one Y chromosome. Because males only have one X chromosome, they only require one X-linked disease gene to display disease. Since females have two X chromosomes, the effect of one X-linked recessive disease gene is masked by the disease gene's normal counterpart on her other X chromosome.

In classic X-linked inheritance males are affected, presenting full clinical symptoms of the disease. Females are usually not affected. Affected fathers can never pass X-linked diseases to their sons. However, affected fathers always pass X-linked disease genes to their daughters. Females who inherit the faulty gene but do not show the disease are known as carriers. Female carriers of

X-linked DMD have a 50% chance to pass the disease-causing gene to each of their children.

It is unusual for female carriers of an X-linked disease to show symptoms of the disease. However, in X-linked EDMD, carrier females can exhibit certain symptoms of the disease. Females have two X chromosomes in each of their body cells. Very early on in fetal development, one X chromosome in each cell of a female is inactivated. The pattern of inactivation is random, so carrier females may express the disease-causing gene in some of their cells. An estimated 10%–20% of female carriers of X-linked EDMD display varying symptoms of the disease. Female carriers can display the dangerous heart symptoms of EDMD. Less commonly, carrier females may show late-onset muscle weakness.

In 1994 it was recognized that the X-linked recessive form of Emery-Dreifuss muscular dystrophy is caused by changes, or mutations, in a gene now known as *EMD*. This gene is located on the long arm of the human X chromosome at a location designated as Xq28. This gene codes for emerin, an amino acid protein. Emerin is an important protein normally found on the inner nuclear membrane of skeletal, cardiac, and smooth muscle cells as well as in other tissues. Emerin is missing from the nuclear membranes of males affected with X-linked EDMD. Emerin is not altered in other neuromuscular disorders.

In some families, EDMD may be inherited in an autosomal dominant pattern and is caused by mutations in the *LMNA* gene. Autosomal dominant EDMD is known as Emery-Dreifuss muscular dystrophy 2 (EDMD2), Hauptmann-Thannhauser muscular dystrophy, and scapuloilioperoneal atrophy with cardiopathy. Autosomal dominant disorders affect both sexes equally. In autosomal dominant conditions a person, male or female, requires only one faulty gene to produce disease. There are no unaffected carriers of EDMD2. In families with EDMD2, both males and females can be affected and father-to-son inheritance of the disease can occur. Every child of a person affected with EDMD2 has a 50% chance of inheriting the disease.

In families with EDMD2, affected members exhibit a later onset of the same symptoms as someone affected with X-linked EDMD. Symptoms begin between the ages of 17 and 42. EDMD2 and X-linked EDMD are caused by changes in different genes on different chromosomes.

Muscle biopsy of patients with EDMD2 show normal emerin levels. In families with EDMD2, the disease is caused by changes, or mutations, in a gene known as *LMNA*. *LMNA* contains the coding for proteins lamin A and lamin C and is located in a specific area on the long

arm of chromosome 1 known as 1q21.2. Like emerin, these lamins are associated with the nuclear membrane. People with autosomal dominant EDMD2 have normal levels of emerin and low levels of these lamin proteins. Emerin and these lamins form an important protein complex in a cell's nuclear membrane. The exact role of this complex is unclear. Scientists theorize that this important complex of proteins stabilizes the nuclear membrane and plays a role in regeneration of muscle fibers.

EDMD of autosomal recessive inheritance has been named Emery-Dreifuss muscular dystrophy 3 (EDMD3). For someone to be affected with an autosomal recessive disease they must inherit two copies of an abnormal or mutated *LMNA* gene, one from each parent. A parent who has only one gene associated with autosomal recessive EDMD is not affected by the disease and is known as a carrier of the disease. Two carriers of autosomal recessive EDMD have a 25% chance of having a child affected with the disorder in each pregnancy. Like EDMD2, EDMD3 is caused by mutations in the *LMNA* gene located on the long arm of chromosome 1 at an area designated as 1q21.2.

Demographics

X-linked EDMD is estimated to occur in 1 in 100,000 births. EDMD2 and EDMD3 are far less common. Only males exhibit full symptoms of X-linked EDMD. EDMD2 and EDMD3 may occur in males and females. X-linked EDMD and EDMD2 have been documented in many countries. There does not appear to be a single founder of these diseases, as many families have distinctly different backgrounds and different disease-causing mutations.

Signs and symptoms

EDMD is recognized by a classic triad of symptoms: contractures at a young age, progressive muscle weakness and degeneration involving the upper arms and lower legs, and cardiac (heart) muscle disease.

Contractures

Contractures, or frozen joints, are a hallmark of all forms of EDMD. A contracture is the abnormal shortening of a body part, usually a muscle or a tendon. This shortening creates joint deformity. Contractures usually begin in childhood or adolescence before any muscle weakness is evident. In most cases, contractures are recognized before patients reach ten years of age.

Contractures may display as flexion or extension deformities. In a flexion contracture a muscle or tendon remains abnormally flexed, permanently bending a body part at a joint. In an extension contracture, a muscle or

KEY TERMS

Amniocentesis—A prenatal test in which a small amount of amniotic fluid is removed from the uterus for testing.

Arrhythmia—Abnormally fast, slow, or irregular heartbeat.

Chorionic villus sampling (CVS)—Prenatal test in which a very small sample of the placenta is taken to test for genetic conditions in the infant.

Contracture—Permanent shortening of a muscle or joint.

Creatine kinase (CK)—An enzyme found in the brain, heart, and skeletal muscles; if elevated amounts are discovered, it can indicate the presence of one of several serious medical conditions.

Pacemaker—A medical device placed in the chest that helps regulate heart rate.

Peroneal—Pertaining to the outer aspect of the leg.

Sex chromosomes—Pair of chromosomes that determine whether an individual is male or female.

Tibialis—Either of two muscles of the calf of the leg.

tendon remains abnormally extended, not allowing a body part to bend at a joint. Affected persons cannot control these contractures and cannot release them at will. Contractures are treated with stretching, physical therapy, bracing, and surgery.

People affected with EDMD often have flexion contractures of the elbows and ankles. Elbow contractures force the elbow to remain bent at an angle. Contractures of the Achilles tendons, or heel cords, force the feet to remain in a pointed toe position. Children with EDMD often walk on their toes due to heel cord contractures. Neck and trunk contractures may also occur, restricting movement of the neck or the entire spine.

Scoliosis is commonly found in patients with EDMD. Muscle weakness and degeneration are slowly progressive, affecting a distinct pattern of muscles. This pattern includes the muscles of the upper arms and the muscles of the lower legs. The biceps (inner upper arm), triceps (outer upper arm), tibialis anterior (inner lower leg), and peroneal (outer lower leg) muscles are commonly involved. Later, the muscles of the shoulder girdle and pelvic girdle, the shoulder and hip area muscles that stabilize and support the attachment of the arms and legs, may also be affected. Additionally, the highly specialized muscle of the heart is at risk for weakness and degeneration.

Heart disorders

Heart disease associated with EDMD may be life-threatening. It is, however, potentially treatable. Not all patients with EDMD develop heart involvement. Any heart involvement often becomes apparent in the second to third decade of life. In rare cases, heart problems may be the first symptom of EDMD. Early recognition of heart involvement is of utmost importance as surgical placement of a pacemaker may be lifesaving.

EDMD is associated with cardiac conduction defects (electrical impulse problems), heart muscle degeneration, and unusual tissues (abnormal fatty and fibrous tissues) growing into the heart. Conduction defects can manifest as heart rhythm disturbances known as arrhythmias or, more seriously, heart block. Heart block is a dangerous situation where the heart is unable to respond correctly to its own electrical system. Arrhythmias and heart block can lead to fainting or even sudden death. One uncommon type of heart conduction problem, total permanent auricular paralysis (TPAP), is relatively specific to EDMD. Scientists have found that 33% of 109 published cases of TPAP were due to EDMD.

The level of skeletal involvement in a patient with EDMD is not indicative of the level of heart involvement. Heart problems can be unpredictable, occasionally leading to sudden death without any prior symptom. In a review of 73 cases of X-linked EDMD, scientists found that 30 patients died suddenly between ages 25 and 39. Frequent careful checkups with a cardiologist (heart specialist) are necessary. Preventive surgical implantation of a pacemaker is often considered.

Female carriers of X-linked EDMD may display some symptoms of disease. They can have the dangerous heart problems or, less commonly, muscle weakness. One case of sudden death of a female carrier of X-linked EDMD has been reported. It is recommended that female carriers of X-linked EDMD have regular examinations by a cardiologist.

Diagnosis

Diagnosis of EDMD is based on the classic triad of distinctive clinical symptoms seen in this disease. A diagnosis based on careful neuromuscular examination may be confirmed with muscle biopsy or DNA testing.

Other special laboratory tests and neuromuscular tests may help physicians to confirm or rule out EDMD. Creatine kinase (CK), a muscle enzyme, is often measured when symptoms of muscular dystrophy are present. CK levels are only mildly elevated in EDMD. Muscle biopsy can show microscopic changes in muscle fibers. Muscle biopsy also allows for a very practical test for X-linked EDMD where muscle tissue is stained with a chemical that binds specifically to emerin. If emerin is

QUESTIONS TO ASK YOUR DOCTOR

- What are the characteristic features associated with Emery-Dreifuss muscular dystrophy?
- Can this disorder be diagnosed by prenatal tests?
- If not, how soon after birth can it be diagnosed?
- What is the basis for making a diagnosis of Emery-Dreifuss muscular dystrophy, and how can the disorder be differentiated from similar conditions?
- What is the prognosis for my child, and what steps can I take to improve that prognosis?

present, X-linked EDMD can be ruled out. If emerin is reduced or absent, X-linked EDMD is diagnosed.

Genetic testing and prenatal diagnosis for X-linked Emery-Dreifuss muscular dystrophy is available on a clinical basis. To perform DNA testing for X-linked EDMD a blood sample is required. This method of testing can diagnose female carriers of X-linked EDMD. Prenatal testing requires fetal cells obtained via amniocentesis or chorionic villus sampling. Once the specific alteration in the gene is identified in an affected family member, female relatives at risk to be carriers can be tested and prenatal diagnosis can be offered. Prenatal testing is performed on DNA extracted from fetal cells obtained by amniocentesis or chorionic villus sampling.

Treatment and management

The muscle and skeletal symptoms of EDMD are treated as they appear. People with EDMD should see a neurologist at least once a year. Stretching and working with a physical therapist is useful in preventing or delaying contractures. Occupational therapy can help patients adapt their activities and environment to their own particular needs. Ankle and foot braces are used to prevent leg deformity. Surgery may be necessary to release contractures. Exercise can help maintain muscle use and overall good health. Affected individuals may eventually require a wheelchair or other adaptive equipment.

Individuals with EDMD require frequent, at least yearly, heart checkups with a cardiologist. Heart symptoms can appear suddenly with disastrous consequences, so patients often have a pacemaker implanted before they have had any serious heart problem. Anti-arrhythmia drugs, diuretics, ACE inhibitors, and blood thinners may help with some of the cardiovascular symptoms associated with EDMD.

Heart transplant has been successful. Relatives of patients with EDMD, especially female carriers of

X-linked EDMD, should also be offered yearly screening for heart involvement via electrocardiography and echocardiography.

Scientists are currently researching gene therapy as a possible treatment for EDMD. *EMD*, the gene known to be involved in the X-linked form of EDMD, is a relatively small, less complicated gene. A small gene with a widespread product such as *EMD* shows great promise for gene therapy.

Prognosis

Without serious heart involvement, most people with EDMD are expected to survive at least into middle age. Slow progression of muscle involvement allows most patients to walk and work until middle age or late adult life. Intellect is not affected.

Encephalocele

Definition

An encephalocele is a defect characterized by the herniation of brain tissue and membranes through an opening in the cranium. The term comes from two Greek words that mean “contents of the skull” and “hernia.” Other terms for encephalocele include *cephalocele*, *craniocoele*, and *cranium bifidum*.

Description

Encephaloceles are classified as neural tube defects (NTDs), which are a group of disorders occurring due to the failure of closure of the neural tube at about week four of fetal development.

Other neural tube defects include anencephaly and spina bifida. Anencephaly results from failure of closure of the cranial end of the neural tube. This is a lethal condition. Spina bifida results from failure of neural tube closure in the spine. Spina bifida is a variable condition that is usually not lethal, but it causes problems with bladder and bowel control and ambulation (walking). It is usually associated with hydrocephalus (water on the brain), which can be treated with a shunt to drain the fluid into the body cavity. Encephalocele is the rarest neural tube defect.

Encephaloceles are classified according to their location. Occipital (arising at the back of the head where the head meets the neck) encephaloceles occur in 75% of cases, with 90% of these occurring at the midline of the skull; parietal encephaloceles in 10%; and anterior encephaloceles (arising from the base of the nose) in 15%. Anterioposterior encephaloceles have a poorer prognosis.

Genetic profile

The genetics of neural tube defects, including encephalocele, were not well understood as of 2021.

Most encephaloceles are sporadic, following a multifactorial pattern (genetic and environmental factors involved) of inheritance. It is known that there is a genetic basis to encephaloceles and other neural tube defects, and it is believed that neural tube defects may be caused by different genetic factors in different subsets of families. Other malformations and/or chromosomal abnormalities are found in at least 60% of patients with encephaloceles. Proof that genetic factors contribute to encephaloceles is that they are known to run in families, and they have been seen in association with some chromosome abnormalities. The number of genes and their locations are still not known.

A composite set of MRI images from a neonate reveals an encephalocele at the vertex of the head. (Living Art Enterprises, LLC/Science Source)

Occipital encephaloceles are associated with several single-gene syndromes, including Meckel syndrome, dyssegmental dwarfism, Knobloch syndrome, Walker-Warburg syndrome, cryptophthalmos, and von Voss-Cherstvoy syndrome. Anterior encephalocele may occur with frontonasal dysplasia. Encephalocele can also be seen in the amniotic band syndrome, a condition that occurs when part of the fetus's body (most often fingers or a limb) becomes entangled in fibrous bands inside the amniotic sac before birth. The bands cause constriction of the entrapped body parts, leading to reduced blood circulation and congenital abnormalities.

Demographics

The frequency of encephalocele has been reported to be between 1 in 2,000 and 1 in 10,000 live births. Anterior encephalocele is more common in Africa, Thailand, and India. Females outnumber males for occipital encephalocele but not for other types.

The incidence of all neural tube defects is different in different parts of the world. It is highest in northern Europe, specifically the British Isles and especially South Wales. In the United States, it is higher on the East Coast than on the West Coast, and it is highest of all in Appalachia. It is also higher among Hispanics than among either non-Hispanic Caucasians or African Americans.

KEY TERMS

Anencephaly—The absence of a major portion of the brain, upper skull, and scalp during fetal development.

Boomerang dysplasia—A lethal genetic syndrome in which fetal bones and cartilage fail to develop normally; the arm and leg bones are bent into the shape of a boomerang. Infants with this disorder die shortly after birth.

Cryptophthalmos—A congenital malformation of the eye in which the eyelid fails to develop, the eye is either missing or rudimentary, and the orbit of the eye is covered by a fold of skin extending directly from the forehead to the cheek.

Frontonasal dysplasia (FND)—A congenital malformation of the face characterized by a wide, flat nose; abnormally widely spaced eyes; and a cleft that runs down the middle of the face across the nose.

Herniation—The abnormal protrusion of an organ or other structure through a defect or natural opening in a membrane, muscle, bone, or other tissue.

Hydrocephalus—A medical condition that occurs when fluid builds up inside the skull and causes the brain to swell. It is sometimes called “water on the brain.”

Knobloch syndrome—A rare genetic disorder characterized by cataracts in the eye, degeneration and detachment of the retina, and occipital encephalocele.

Meckel syndrome—A fatal genetic disorder characterized by occipital encephalocele as well as other central nervous system defects, large polycystic kidneys, and incompletely developed lungs.

Neural tube defects (NTDs)—A group of disorders in which an opening in the brain or spinal cord persists after the fourth week of fetal development.

Spina bifida—A birth defect in which there is incomplete closure of the spine and the meninges (membranes) over the spinal cord.

von Voss-Cherstvoy syndrome—A very rare genetic disorder characterized by encephalocele, brain abnormalities, upper limb defects, and malformations of the urogenital tract.

Walker-Warburg syndrome—A congenital form of muscular dystrophy that may be accompanied by encephalocele as well as muscular weakness and other abnormalities of the eyes and brain.

The rate of sporadic neural tube defects in the general population is about 1 in 1,000. The chance of a recurrence of a neural tube defect after having an affected child is 2%. After two affected children the risk is 10%. The chance for an affected person to have an affected child is 4%. The chance for a second-degree relative to have an affected child is 0.5%. Third-degree relatives do not have an increased risk. Recurrence risks are given for neural tube defects as a group. A family with a previous child with anencephaly could have a child with spina bifida or encephalocele (the types do not “breed true” in families).

Care must be taken to be sure that the neural tube defect in the family is sporadic and not associated with a genetic syndrome, which would have a higher risk of recurrence.

Signs and symptoms

Symptoms of encephalocele may include hydrocephalus, spastic quadriplegia (paralysis of all four limbs), developmental delay, intellectual disability, growth retardation, uneven gait (ataxia), or seizures.

The size of the cerebral and skull abnormalities associated with encephaloceles is variable. Large

encephaloceles are usually associated with microcephaly (abnormally small head). Microcephaly is usually associated with intellectual disability.

Occipital encephalocele may be asymptomatic. If the ventricles (a set of four interconnected cavities in the brain) are involved, hydrocephalus may occur. Anterior encephalocele may progress in size and may be solid, cystic, or both. There may be microcephaly and/or hydrocephaly, ocular hypertelorism (wide-spaced eyes), and cleft palate. There may be problems with vision, breathing, and feeding in patients with anterior encephaloceles. Many patients have intellectual disability.

Diagnosis

Encephaloceles can be diagnosed by ultrasound examination at around 13 weeks gestation. Ultrasound examination is a screening test, the quality of which is affected by many factors including the machine used, skill of the operator, size and location of the lesion, and position of the fetus.

It is not likely that maternal serum alpha-fetoprotein testing (AFP) or amniocentesis would detect encephalocele. Alpha fetoprotein is a normal serum protein

QUESTIONS TO ASK YOUR DOCTOR

- Please describe the physical characteristics associated with my child's encephalocele.
- Are there steps that we can take before the child's birth to prepare for this disorder?
- What treatments are available to treat the condition after birth?
- What information can a genetic counselor provide my spouse and me about my child's genetic disorder?

produced by the fetal liver. The AFP normally stays within the fetus, with a small amount present in the amniotic fluid from the fetal urine. When there is an "open" neural tube defect, there is a high amount of AFP in the amniotic fluid and the maternal serum. Although encephalocele is a neural tube defect, AFP testing on maternal blood or amniotic fluid detects only open neural tube defects. Encephaloceles are closed neural tube defects, meaning they are covered by a thick covering. This covering does not allow the AFP to leak into the maternal blood or the amniotic fluid in increased amounts that would be detected by the aforementioned tests. Pregnancies in which an encephalocele is diagnosed should be offered an amniocentesis and amniotic fluid biochemistry to better understand the cause of the disorder.

CT scan can be used to determine the contents of the encephalocele once the baby is born. Some centers offer fetal MRI to attempt to classify the encephalocele prior to delivery. This is usually done at 22 weeks gestation. MRI is considered superior to CT scanning for detecting and identifying the soft-tissue contents of an encephalocele.

Treatment and management

Surgery is the mainstay of treatment for infants with encephaloceles. It is usually performed in the time period shortly after birth if the encephalocele does not have a protective layer of skin; otherwise, surgical treatment can be delayed until the fourth month of life. The primary goals of surgery are to replace the protruding tissues within the skull, remove the sac, and correct any defects of the skull and facial features. Hydrocephalus may require the placement of a shunt. Other treatment is primarily supportive.

Nutrition, specifically deficiency of folic acid, has been implicated as causing an increased risk of neural tube defects. All women of childbearing age should take 0.4 mg of folic acid per day to reduce the risk of birth

defects. Women with a previous child with a neural tube defect should take 4.0 mg of folic acid on a daily basis. This amount has been shown to reduce the recurrence risk for neural tube defects by 50%. The Centers for Disease Control and Prevention (CDC) reported in 2015, however, that the recommendation of folic acid supplements is not followed by many pregnant women and that there are still many missed opportunities for prevention of neural tube defects.

Prognosis

Size, location, and contents of the encephalocele determine the outcome for the child. Anterior encephaloceles have a much better prognosis than posterior. Mortality due to occipital encephalocele is reported at about 30% if hydrocephalus is present and 2% if it is not. For all types of encephalocele with hydrocephalus, the mortality rate is 60%. Most patients with parietal encephalocele have associated brain malformations, and intellectual disability occurs in 40%. Massive occipital encephaloceles with microcephaly have a mortality rate of nearly 100%. Patients with encephaloceles that contain a single frontal lobe are more likely to have normal intelligence without hydrocephalus. Posterior encephaloceles have a poorer prognosis if they contain large amounts of the contents of the posterior fossa (an area of the brain at the back of the head), especially the brain stem. Complications such as hemorrhage or air embolism (stroke) can occur.

Epidermolysis bullosa

Definition

Epidermolysis bullosa (EB) is a group of rare inherited skin diseases that are characterized by the development of blisters after minimal pressure to the skin. Blistering often appears in infancy in response to simply being held or handled. In rarer forms of the disorder, EB can be life-threatening. There is no cure for EB. Treatment focuses on preventing and treating wounds and infections.

Description

There are three major forms of EB and at least 16 subtypes. The three major forms are EB simplex, junctional EB, and dystrophic EB. EB can range in severity from mild blistering to disfiguring, disabling, or life-threatening disease. Physicians diagnose the form of the disease based on where the blister forms in relation to the epidermis (the skin's outermost layer) and the deeper dermis layer. EB can sometimes affect the mouth, teeth, eyes, nails, esophagus, lungs, and muscles, in addition to the skin.

Genetic profile

The three types of EB are caused by different genetic mutations. Most subtypes of EB simplex are caused by autosomal dominant mutations in the genes responsible for keratin 5 and keratin 14. Keratins are proteins that provide the epidermis with its structural scaffolding. Mutations that result in defective keratin and scaffolding cause the skin to fall apart and blister. Autosomal dominant inheritance means that the disorder occurs in the presence of a single mutated gene, inherited from one parent, even if the gene inherited from the other parent is normal.

Junctional EB is caused by mutations in the genes that encode the proteins collagen17 or laminin-5. These proteins help hold the skin together, and if they are absent or abnormal, the skin can easily separate and blister. Junctional EB is inherited in an autosomal recessive pattern, meaning that two mutated genes, one from each parent, are necessary for the disorder to occur.

(Harout Tanielian/Science Source)

Dystrophic EB is caused by mutations in the *COL7A* gene that produces collagen7. These mutations can be either dominant or recessive. Collagen7 is protein in the fibers anchoring the epidermis to the dermis. Abnormal collagen causes fragile, easily separated skin that forms blisters. Dominant dystrophic EB usually causes mild-to-moderate skin blistering with only slight blistering of the mouth, esophagus, and gastrointestinal tract. Recessive dystrophic EB is the most severe and chronic form of EB and can be fatal.

Demographics

EB is often not accurately diagnosed, so its prevalence is unclear. However, it is estimated to affect

between 25,000 and 50,000 people in the United States and to occur in 20 newborns per million.

Signs and symptoms

Localized EB simplex, the most common form of EB, is the least serious form of the disease. In most affected individuals, the blisters are mild and do not scar after they heal. Some forms of EB simplex affect just the hands and feet—the areas of the body subject to the most trauma. Generalized EB simplex causes widespread blistering, as well as hair loss and missing teeth.

The many forms of junctional EB all cause widespread blistering. Although this form of EB does not lead to scarring, skin often shrinks on the areas most prone to blistering, such as the elbows and knees. In one form of junctional EB, called gravis junctional EB of Herlitz, the blistering can be so severe that affected infants may not survive due to massive infection and dehydration.

Dystrophic EB varies greatly in severity, but more typically affects the arms and legs. Recessive dystrophic EB develops at or shortly after birth, and there is extensive skin and internal blistering. Recurrent scarring of the fingers and toes can cause a deformity called pseudo-syndactyly, and the hands and arms may become fixed in stiff positions (contractures). Blistering of the mouth, esophagus, and digestive tract can make eating very painful.

Diagnosis

Physicians and researchers distinguish between the three major types of EB based on which layer of the epidermis separates from the deeper dermis layer of the skin below. Patients suspected of having EB will have a fresh

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Dermis—The layer of skin beneath the epidermis.

Epidermis—The outermost layer of the skin.

Keratin—A tough, water-insoluble protein found in the nails, hair, and the outermost layer of skin. Human hair is made up largely of keratin.

Laminin—A protein in connective tissue that is important for cell adhesion.

Pseudosyndactyly—A joining together of the fingers or toes from scarring that can occur with severe forms of epidermolysis bullosa.

blister biopsied for examination under an electron microscope or under a conventional microscope using a technique called immunofluorescence, which helps to map the underlying structure.

Genetic diagnosis of the underlying gene mutation may be available, especially if a family gene mutation has been identified. However, parents or siblings may show no sign of the disorder, either because the parents are carriers of the recessive trait and have no symptoms or because it is caused by a new genetic mutation in the individual.

Treatment and management

Mild forms of EB may require little or no treatment. People with the Weber-Cockayne subtype of EB simplex—the most common form of EB—almost never even seek medical care. However, severe forms require intensive daily care by family members, similar to care for burn victims. Because the skin is very fragile, extreme care must be taken with dressing changes to prevent further damage. Tape cannot be applied directly to the skin, and bandages should be soaked off. Infection is a major concern, so a topical antibiotic, such as bacitracin, mupirocin, or sulfadiazine, should be applied routinely. The anticonvulsant phenytoin is sometimes effective against recessive dystrophic EB, because it decreases production of an enzyme that breaks down collagen. Children with severe EB usually require treatment from a team of specialists.

QUESTIONS TO ASK YOUR DOCTOR

- How do the various types of epidermolysis bullosa differ from each other?
- How is this genetic disorder transmitted from one generation to the next?
- I have a child with epidermolysis bullosa; what are the chances that I will have a second child with the same disorder?
- Is genetic screening available for the gene mutations that cause epidermolysis bullosa?

Prognosis

The prognosis for EB depends on the type and subtype. Individuals with EB simplex generally live normal lives. The severity of the junctional and dystrophic forms of EB can vary greatly. Some forms of junctional EB improve with age. Infants affected with some forms of EB often do not survive infancy or suffer from severe scarring and disfigurement.

Epigenetic inheritance

Epigenetic change is a change in phenotype (observable characteristics) without a change in genotype (the genetic makeup of an organism). Epigenetic changes are heritable, which means they may be passed from one generation to the next, and potentially reversible changes in gene function that occur without a change in the sequence of DNA in an organism. Instead, these changes result from how genes are expressed—the activation and deactivation of those genes.

Epigenetic inheritance, specifically the inheritance of genetic control markers by offspring, has gained the attention of evolutionary scientists. This transgenerational inheritance is initiated during gamete formation. Epigenetic transcriptional control mechanisms rather than the genetic code are responsible for this form of inheritance.

Environmental factors induce the markers for epigenetic control of development and cellular differentiation

in higher life forms. Most marks are removed in gamete formation, and some marks are heritable. The inheritance of acquired characteristics, or Lamarckism, may explain newly appreciated heritable changes in phenotype due to epigenetics. There has been renewed interest in Lamarckism, proposed by French zoologist Jean-Baptiste Lamarck (1744–1829) and supplanted by Mendelian genetics in view of increased understanding and appreciation of epigenetics. Evolutionary theory must adapt to account for transgenerational epigenetic inheritance.

Epigenetic markers and controls

Epigenetic markers act like punctuation in the way that DNA will be read and acted upon. An exclamation point tells the cell to upregulate or strongly express a gene. A comma tells the cell to slow or pause the process, down-regulating a gene, and a period stops the process entirely, deactivating or silencing the gene. Epigenetic markers are added by writer proteins and may be modified or removed by editor proteins, and some are inherited.

DNA methylation and histone acetylation patterns that regulate gene expression may be inherited, and transcriptional interference through the transmission of small interfering RNAs can alter the phenotype of the zygote. The third type of transgenerational epigenetic inheritance is the formation of metabolic loops. In loops, a gamete's mRNA or protein product controls its own gene expression at the transcription level. The zygote perpetuates the control loop to affect inheritance after fertilization. Each of these mechanisms is found in mammals.

The epigenome comprises the DNA and a large series of proteins and small molecules that bind to the double helix. They serve to alter gene activity. Epigenetics are inherited phenotypical changes to the resulting

Epigenetic markers on a DNA double helix including a chromosome and cell. Epigenetics is the study of heritable phenotype changes that do not involve alterations in the DNA sequence. (Medicalwriters/Science Source)

KEY TERMS

DNA methylation—The addition of methyl groups to DNA, which suppresses gene transcription. Suppressing genes is the basis of epigenetics.

Histone acetylation—The addition of an acetyl group, a three-carbon molecule, at one end of a histone molecule. This DNA acetylation alters gene function without changing any DNA base pairings.

Phenotype—The observable physical properties of an organism; its appearance, behavior, actions, and traits.

chromatin without alterations to the genetic sequence. The phenotypical changes are expressed as changes in cellular or physiological activity or changes in gene expression. Both environmental and developmental forces can cause phenotypic changes that are heritable to daughter cells.

Chemical mechanisms of altering phenotype include DNA methylation, histone acetylation, inhibition of gene expression by RNA, and the binding of repressor proteins to silencer sequences. Any of these can last several cell division cycles, and some may survive gamete formation. For these covalent modifications to the epigenome, a series of enzymes creates and maintains patterns of these markers.

Promoters in different cell types have different nucleosome positions. This variation is a result of histone acetylation patterns and results in differential gene expression and cell differentiation. Nucleosomes block transcription by binding to DNA. Their placement can be influenced by DNA methylation too, and those positions are sometimes inherited.

Molecular sequencing techniques sensitive to DNA methylation and protein chemistry techniques that detect acetylated histones have facilitated rapid advancement of our understanding of transgenerational epigenetic inheritance. For example, we now know that natural populations display many epigenetic variations or a high epimutation rate. Epimutations in phenotype can create heritable variations that can ultimately enable adaptation alongside genetic mutations and profoundly influence evolution.

The fate of epigenetic markers

Epigenetic modification within cells is reset during meiosis. Most methyl groups are removed from DNA, and histone acyl groups are absent. Removal or retention

mechanisms of these markers in either gamete affect inheritance. After fertilization, acetylated histones from sperm are replaced with unmodified histones from the female's cytoplasm, and male DNA is demethylated, thus deprogramming it. Maternal DNA remains methylated and distinguishable from male DNA. Then, during DNA replication, DNA polymerase is coupled to enzymes that reproduce the DNA methylation and histone acetylation patterns from the parent cell.

Contribution to phenotypes

Transgenerational epigenetic inheritance can evolve if the environment is stable across generations. With selective pressure, genetic change may ultimately follow. There is evidence of inheritance that is stable for generations shaping human lives. Now, the relative importance of genetic and epigenetic inheritance is subject to debate.

Epigenetic inheritance in humans

Near the end of the Civil War in 1865, conditions in the Confederate prisoner of war (POW) camps were inhumane. The overcrowding of Union Army prisoners was severe, and prisoner death rates climbed. The traumatic nature of the experience affected survivors for life. When they returned to society, their health, job prospects, and life expectancy suffered. Researchers contend that the prisoners' offspring inherited these impediments.

They studied the health records of nearly 4,600 descendants of former prisoners who had not themselves suffered the hardships of a POW camp. These descendants suffered higher rates of mortality than the wider population. The POWs passed on some element of their own trauma to their offspring.

Many deaths in the prisoners' offspring were due to higher rates of cerebral hemorrhage and cancer. The daughters of former POWs did not suffer these effects, though. Only sons born after their fathers' trauma were affected in a sex-linked pattern, suggesting the epigenetic change happened on the X chromosome during or after the trauma.

Revising evolutionary theory

That the genetic code is not the sole basis of inheritance is evident. Environmentally induced phenotypes can control gene expression and be passed for several generations as epigenetic markers are passed. While epigenetic regulation of gene expression occurs during the differentiation of somatic cells and in response to the environment, inheritance of these markers by the offspring constitutes transgenerational epigenetic inheritance.

Epigenome

The epigenome consists of DNA and the small molecules and proteins that bind or attach to the double helix and modify or mark it by tightly wrapping specific genes to deactivate them and relaxing others to activate them, enabling their expression. Epigenomics is the study of these markers that switch parts of the genome on and off at specific times and locations, and the factors that influence them, which in many cases may be passed down to from generation to generation.

Epigenetics are inherited phenotypical changes to the resulting chromatin without alterations to the genetic

sequence. The phenotypical changes are usually expressed as changes in cellular or physiological activity or change in gene expression. Both environmental and developmental forces can cause phenotypic changes that are heritable to daughter cells.

Chemical mechanisms of altering phenotype include DNA methylation, histone acetylation, inhibition of gene expression, and the binding of repressor proteins to silencer sequences. Transcriptional repression due to silencer binding can last several cell division cycles.

In multicellular life, cellular differentiation is driven by the state of the epigenome. Stem cells differentiate to become the cell lines of the embryo that then develop into more fully differentiated cells. Through the activation or inhibition of certain genes, the epigenome orchestrates its own cell's phenotypes.

Molecular characteristics of the epigenome

Transgenerational epigenetic inheritance occurs when the cell divides, and the epigenome structure responsible for a phenotypic change is seen in a gamete. The egg or sperm will carry the modification to next generation.

Processes of the epigenome

Epigenetic processes include paramutation, imprinting, bookmarking, gene silencing, X chromosome inactivation, positional effects, DNA methylation, maternal effects, damage due to teratogens (substances that may produce physical or functional defects in the human embryo or fetus after exposure during pregnancy), the regulation of histone modifications and heterochromatin.

DNA damage and changes in the epigenome

DNA is damaged about 60,000 times a day per cell naturally. The damage is usually repaired. Epigenetic changes, however, can endure the cell replication process. Double-strand DNA breaks can lead to DNA methylation and gene repression. Breaks can also lead to changes in modification of histone genes that alter chromatin structure and gene activity.

Enzymes that accumulate at the site of DNA breakage recruit chromatin remodeling proteins that change the structure of nucleosomes and the activity of DNA repair genes. DNA damage can also lead to hypomethylation of the chromatin, alternate protein binding activity, and gene transcription.

Building the epigenome

There are several types of inheritance systems that play a part in cell memory.

KEY TERMS

DNA methylation—The addition of methyl groups to DNA, which suppresses gene transcription. Suppressing genes is the basis of epigenetics.

Histone acetylation—The addition of an acetyl group, a three-carbon molecule, at one end of a histone molecule. This DNA acetylation alters gene function without changing any DNA base pairings.

Paramutation—a heritable change in the expression of one allele that results from an interaction of this allele with another allele for the same trait. The paramutation-affected allele can be passed to subsequent generations.

Phenotype—The observable physical properties of an organism; its appearance, behavior, actions, and traits.

Transcriptional repression—Methods that inhibit transcription such as protein binding to promoters to impede binding of RNA polymerase.

Covalent Modifications

Covalent modifications of either DNA, such as cytosine methylation and the hydroxy methylation (introduction of a hydroxymethyl group into a compound) of histone proteins play central roles in many types of epigenetic inheritance. Chromatin remodeling includes a change in the way DNA wraps around histone proteins. It can affect gene expression and can be inherited.

Histone modifications occur along the whole protein. The unstructured N-termini of histones (called histone tails) are most frequently modified, though. These modifications include numerous covalent bonds. Acetylation of histones changes their charge and reduces their affinity for DNA, leaving room for transcription factors to assemble. So, gene expression is activated.

Other chromatin remodeling proteins may bind in the region of acetylated histone tails and alter transcription rates. Methylation of histone 3, for example, is associated with condensation of the chromosome to heterochromatin.

Multiple modifications can work together to change the structure of nucleosomes and chromatin. 5-methylcytosine is deaminated naturally and sometimes changed to thymine by the mismatch repair system. Replacement of cytosine with thymine reduces the number of methylation target sites on chromosomes. Then, enzymes responsible for methylation work to add a methyl group to newly synthesized strands replicating the parent strand pattern.

Chromosomes can adopt stable alternate states with stable gene expression levels that are heritable based on methylation patterns of histones. Methylation patterns are established and maintained by at least three methyltransferases and two demethylation enzymes.

Epigenetic effects of RNAs

For some RNA transcripts, transcription factor activity of the proteins they encode acts to recruit the transcription complex. RNA signaling includes differential recruitment of chromatin-modifying complexes and DNA methyltransferases to specific loci by RNAs during differentiation and development. For some genes, epigenetic changes are mediated by the production of differently spliced splice transcripts, or by formation of double-stranded RNA (RNAi). Descendant cells inherit these changes. RNA can also spread to other cells by diffusion. RNA from sperm and to a greater extent the egg alters gene expression in several generations of offspring.

Micro RNAs are non-coding transcripts less than 30 nucleotides long. As of 2021, more than 2,000 microRNAs (miRNAs) have been cataloged. One controls transcription of 100 to 200 genes by affecting the degradation of their transcripts. In turn, miRNAs can be epigenetically controlled through DNA methylation and histone binding.

Nucleosome placement

Promoters in different cell types have different nucleosome positions, resulting in differential gene expression and cell differentiation. Nucleosomes block transcription by binding to DNA. Their placement can be influenced by covalent modifications such as DNA methylation, and those positions are sometimes inherited.

Epigenetics during mammalian development

In mammals, most cells irreversibly differentiate, with only stem cells retaining the potential to differentiate into several cell types. Epigenetic changes can result from environmental exposures. For example, maternal dietary supplementation with genistein causes epigenetic changes affecting expression of the genes that affect coloration and cancer development. Research on the impact of other known teratogens and carcinogens (cancer-causing agents), on methylation signatures is underway.

Some epigenetic inheritance can endure the reproductive process and become generational. Although most of these multigenerational epigenetic traits are lost over

several generations, they are another aspect of evolution and adaptation. Epigenetic inheritance can differ from traditional genetic inheritance. However, rates of epigenetic changes, or epimutation, can be much faster than rates of mutation, and those mutations are usually easily reversed.

Epilepsy

Definition

Epilepsy is a chronic (persistent) disorder of the nervous system. The primary symptoms of this disease are periodic or recurring seizures that are triggered by sudden episodes of abnormal electrical activity in the brain. The term "seizure" refers to any unusual body functions or activities that are under the control of the nervous system.

Description

The word "epilepsy" is derived from the Greek term for seizure. Seizures can involve a combination of sensations, muscle contractions, and other abnormal body

functions. They may appear spontaneously—without any apparent cause—or they can be triggered by a specific type of stimulus such as a flashing light. Specific cases of epilepsy may result from known causes, such as brain injury, or may have no apparent cause (referred to as idiopathic epilepsy). Idiopathic epilepsy may be initiated by a combination of genetic and environmental factors.

An epileptic seizure involves a transient (temporary) episode of abnormal electrical activity in the brain. During a seizure, many nerve cells within a specific region of the brain may begin to fire at the same time. This activity may then spread out over other parts of the brain. In addition to abnormal physical symptoms, seizures can bring on emotions ranging from fear, anger, and rage to joy or happiness. During a seizure, patients may experience disorientation, spontaneous sensations of sounds, smells, visions, and distorted visual perception—such as misshapen objects and places.

Epilepsy can be caused by some event or condition that results in damage to the brain such as strokes, tumors, abscesses, trauma (physical injury), or such infections as meningitis. Epilepsy can also be triggered by inherited (genetic) factors or some form of injury or trauma at birth. The causes of epilepsy vary somewhat by age group, however. Genetic factors, head trauma, and congenital malformations of the brain are the most common causes in children. Head trauma is the most common cause in young adults. Head trauma, tumors, and stroke are the leading causes in middle-aged adults, and stroke and Alzheimer's disease are the most common causes in older adults.

Symptoms of this disorder can appear at any age. Seizures can damage and destroy brain cells, and scar tissue can develop in the section of brain tissue where seizures originate.

There are many forms of epileptic seizures. The parts of the body that are affected by a seizure and the distinctive characteristics, duration, and severity of the symptoms may be used to distinguish each type of epilepsy. Patients can experience more than one type of seizure. The nature of the symptoms depends on where in the brain the seizure originated and how much of the brain is involved. Seizures can be classified as either generalized or partial. Partial seizures involve abnormal activity in a specific region of the brain.

Generalized (also called tonic-clonic) seizures last about two minutes and are the result of abnormal electrical activity that spreads out over both sides or hemispheres of the brain. They were formerly referred to as grand mal seizures. The patient will usually lose consciousness and fall during the episode. The term "tonic"

Neurosurgery to correct epilepsy. At center is the surface of the cerebrum. Black sutures are attached to the meninges (membranes) that surround the brain. The surgeon holds an electrode to be implanted into the brain to control seizures. (*John Greim/Science Source*)

refers to the first phase of a generalized seizure in which the body muscles become taut or stiff. This phase is followed by the strong, rhythmic muscular contractions (convulsions) of the clonic phase. Sometimes a patient's breathing may be hampered by a brief stoppage of the respiratory muscles, causing the skin to develop a bluish tinge due to lack of oxygen.

Epileptic seizures can also be classified as complex or simple. Complex seizures generally involve a loss of consciousness, whereas simple seizures do not. Simple partial seizures can start out localized (focal) and then evolve into secondary generalized episodes in which the initial abnormal electrical activity spreads to involve other parts of the brain. Patients may actually remember the physical and psychological events that occur during a simple seizure, such as the types of movement, emotions, and sensations, but they frequently are completely unaware of the event. Partial seizures are more common in adults.

An absence seizure (once called *petit mal*) typically results in brief periods of lack of awareness and some

abnormal muscle movement. The patient usually does not fall during the seizure episode but may become absent-minded and unresponsive. They may also appear to be staring into space. Absence seizures last about five to ten seconds.

How seizures affect a person's memory depends where in the brain seizures occur. Seizures can interfere with learning, storage, and retrieval of new information. For example, a form of epilepsy that produces seizures in the temporal lobe of the brain can cause a serious deterioration (loss) of memory function. Early treatment can help prevent or reduce memory loss.

In some forms of epilepsy, seizures can be triggered by a particular mental—or cognitive—activity. For example, the simple activity of reading aloud can trigger a seizure in patients with reading epilepsy. Symptoms include face muscle spasms. In medical terms, this type of epilepsy is referred to as *idiopathic localization-related epilepsy*. This term means that seizures occur in one part of the brain (in this case, the temporal lobes) and that there is no apparent cause that brought on the disorder.

Genetic profile

Genetic factors contribute to about 40% of all epilepsy cases. Most of the generalized epilepsy syndromes and some of the partial epilepsy syndromes have an inherited component. Medical researchers suggest that at least 500 genes may somehow be involved in the development of various forms of epilepsy. As of 2021, 126 epilepsy-associated genes or loci are listed in the Online Mendelian Inheritance in Man database. Most of these genes cause or contribute to a wide range of seizure and epilepsy types, severities, intellectual functioning, and other conditions. Some of them can make people with epilepsy more susceptible or sensitive to environmental factors that initiate or start seizures. Only a few types of epilepsy, however, are thought to be monogenic (caused by just one gene). Different mutations may lead to abnormal brain development or progressive degeneration of brain tissue. Some gene mutations make nerve cells hyperexcitable. These abnormal nerve cells can trigger outbursts of abnormal patterns of electrical activity that can initiate an epileptic seizure.

Specific gene locations called gene markers have been linked to various forms of the disease, such as

juvenile myoclonic epilepsy. However, researchers have discovered that some individuals who possess this gene do not develop symptoms of this disease. In some pairs of identical twins with this gene, one twin might appear normal while the other develops typical symptoms of epilepsy. Thus, genetic inheritance seems to be just one of many factors that influence the possibility of developing epilepsy symptoms. Some genetic mutations may also reduce the effectiveness of antiepileptic medication. One of the major goals of epilepsy research is to determine how a patient's genetic makeup can influence their response to drug therapy.

In 2017, the International League Against Epilepsy (ILAE) issued a revised classification of the epilepsies and divided them into categories according to levels of diagnosis: seizure type, epilepsy type (focal, generalized, combined generalized and focal, and unknown) and epilepsy syndrome as well as etiology (the cause or causes), reflecting recent advances in diagnosis and genetics:

- **Seizure type**—Seizures are classified into focal onset, generalized onset, and unknown onset.
- **Epilepsy type**—The categories are generalized epilepsy, focal epilepsy, combined generalized and focal epilepsies,

and unknown, which indicates that the clinician is unable to determine whether the type is generalized or focal, because there is not enough information.

- Epilepsy syndrome refers to a cluster of features involving distinct seizure types, EEG, and imaging features that tend to occur together. A syndrome often has a typical age at onset, intellectual and psychiatric disorders, seizure triggers, and sometimes prognosis.

Genetic syndromes that include seizure disorder

Genetic syndromes in which seizure disorder is part of the clinical picture include Angelman syndrome, caused by a deletion in the long arm of the maternal form of chromosome 15 at 15q11.2-q13; Rett syndrome, caused by mutations in the *MECP2* gene on the long arm of the X chromosome at Xq28; Pitt-Hopkins syndrome, caused by mutations in the *TCF4* gene on the long arm of chromosome 18 at 18q21.1; and tuberous sclerosis complex, caused by mutations in the *TSC1* gene on the long arm of chromosome 9 at 9q34.13 or the *TSC2* gene on the short arm of chromosome 16 at 16p13.3.

Two other genetic syndromes that include seizures are Sturge-Weber syndrome, which is thought to be associated with mutations in the *GNAQ* gene on the long arm of chromosome 9 at 9q21.2; and Prader-Willi syndrome, caused by a deletion in the long arm of the paternal form of chromosome 15 at 15q11.2-q13.

Chromosomal deletion/duplication syndromes

There are three chromosomal duplication/deletion syndromes in which seizures are a prominent characteristic. They include chromosome 22q deletion syndrome, in which genetic material lost from the long arm of chromosome 22 at 22q11.2 results in congenital heart disease, facial anomalies, and immune system deficiencies as well as seizures. This deletion syndrome has been variously known as DiGeorge syndrome, Shprintzen syndrome, and velocardiofacial syndrome.

The second disorder in this category is Wolf-Hirschhorn syndrome, caused by deletions in the short arm of chromosome 4 at 4p16.3. This syndrome is accompanied by growth retardation and some intellectual disability as well as seizures.

The third deletion syndrome is 1p36 deletion syndrome, in which a deletion on the short arm of chromosome 1 results in patients with an abnormally small head (microcephaly) and misshapen facial features as well as seizures.

Metabolic disorders

Zellweger syndrome is a disorder caused by mutations in any of several *PEX* genes, which code for

peroxins, proteins that are needed for the normal assembly of peroxisomes, organelles within cells that break down very long-chain fatty acids and some types of amino acids. The *PEX1* gene is located on the long arm of chromosome 7 at 7q21.2; the *PEX2* gene is located on the long arm of chromosome 8 at 8q21.11; the *PEX5* gene is located on the short arm of chromosome 12 at 12p13.31; the *PEX10* gene is located on the short arm of chromosome 1 at 1p36.32; and the *PEX26* gene is located on the long arm of chromosome 22 at 22q11.21. Children with Zellweger syndrome typically suffer from loss of liver function as well as seizures and usually die within their first year.

Other genetic metabolic disorders associated with seizures include lysosomal storage diseases and disorders of glycosylation.

Mitochondrial disorders

There are two genetic disorders in this group that have seizures as a presenting symptom. One is mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome, which is caused by mutations in the genes in mitochondrial DNA—most often the *MT-TL1*, *MT-ND1*, and *MT-DN5* genes. These mutations impair the ability of the mitochondria to convert simple sugars and oxygen to energy and to make proteins.

The second disorder in this group is myoclonic epilepsy with ragged red fibers (MERRF) syndrome, which derives its name from the clumps of diseased mitochondria that accumulate in muscle fibers and appear ragged and red in color when stained with Gömöri trichrome stain. MERRF syndrome results from mutations in the *MT-TK*, *MT-TL1*, *MT-TH*, *MT-TS1*, *MT-TS2*, and *MT-TF* genes.

Single-gene mutations

Single-gene mutations associated with epilepsy include the following types of epilepsy:

- Autosomal dominant nocturnal frontal lobe epilepsy: caused by mutations in the *CHRNA4* gene on the long arm of chromosome 20 at 20q13.33; the *CHRN2* gene on the long arm of chromosome 1 at 1q21.4; and the *CHRNA2* gene on the short arm of chromosome 8 at 8p21.2.
- Benign familial neonatal seizures are caused in newborns by mutations in the *KCNQ2* gene on the long arm of chromosome 20 at 20q13.33 or the *KCNQ3* gene on the long arm of chromosome 8 at 8q24.22.
- Generalized epilepsy with febrile seizures has been traced to mutations in the *SCN1A* gene on the long arm of chromosome 2 at 2q24.3; the *SCN2A* gene, also on the long arm of chromosome 2 at 2q24.3; and the *SCN1B* gene on the long arm of chromosome 19 at 19q13.12.

- Mutations in the *GABRG2* gene on the long arm of chromosome 5 at 5q34 are associated with both generalized epilepsy with febrile seizures and familial febrile seizures.

Demographics

Epilepsy affects about 1% of the population in North America by age 20 and 3% by age 70; one in 26 Americans will develop epilepsy over the course of a lifetime. Approximately three million Americans and 65 million people throughout the world have epilepsy. It is the second-most common neurological disorder and affects both sexes and all races and ethnic groups; however, it is slightly more common in males than in females. The highest incidence is in children younger than age 10 and adults older than age 70.

Epilepsy is more common in Asia and Africa than in Europe and North America because of the higher rates of traumatic injury and infectious diseases (particularly parasitic diseases) in the developing world. Worldwide, the most common cause of epilepsy is infection. Epilepsy may arise in a wide range of conditions including neurocysticercosis, tuberculosis, HIV, cerebral malaria, subacute sclerosing panencephalitis, cerebral toxoplasmosis, Zika virus, and cytomegalovirus. It also may develop after an infectious disease has resolved. For example, following viral encephalitis (inflammation of the brain caused by a virus such as influenza, herpes simplex, measles, mumps, rubella, rabies, chickenpox, or West Nile virus), some patients develop seizure disorders.

Signs and symptoms

Patients who have been diagnosed with epilepsy may have little warning that they are about to experience an epileptic seizure. Some patients experience an unusual feeling, or aura, that can act as a warning that an episode is about to start. Auras generally precede actual seizures. An aura may take the form of an unusual sensation such as a fearful feeling, a mental image, or a peculiar taste, smell, or sound. A period of confusion or stupor known as the post-ictal period may follow a seizure. Getting a good night's sleep is a common problem for young children with epilepsy. Lack of sleep can then lead to behavior problems and drowsiness during the daytime.

Diagnosis

Diagnosis of epilepsy is complicated by several factors, such as the fact that people can have a so-called first seizure caused by low blood sugar, sleep deprivation, eclampsia of pregnancy, kidney or liver dysfunction, or electrolyte disturbances. Many people who have a first seizure never have a second one; doctors therefore prefer

not to give antiseizure medications to a patient in this category unless he or she has other risk factors for epilepsy (including family history). In addition, conditions such as alcohol withdrawal and psychogenic non-epileptic seizures (PNES) may be difficult to distinguish from true seizures without EEG testing. For these reasons, epilepsy is defined as the occurrence of at least two unprovoked seizures occurring more than 24 hours apart.

Early symptoms of epilepsy include excessive staring, easy distraction, and difficulty maintaining attention. To confirm the diagnosis, doctors look for neurological (nervous system) abnormalities such as speech or vision defects or defects in brain structure or other parts of the nervous system. The goal of the diagnostic testing is to identify where the seizures are originating. EEGs (electroencephalographs) are used to monitor electric activity—patterns of nerve impulses in the brain. A type of neuroimaging called magnetic resonance imaging (MRI) is also used extensively to try to pinpoint the location and type of abnormalities (referred to as lesions) in brain structures that cause episodes of epileptic seizures. In some cases, videotaping seizures and monitoring the patient's EEGs may be useful for identifying the specific type of epilepsy.

Idiopathic epilepsy—those cases for which no specific cause can be identified—is presumed to have a genetic basis. As of 2021, molecular genetic testing was available for more than 80 genes linked to various types of epilepsy, and hundreds of other genes are associated with genetic syndromes that have seizures as a symptom. However, there is no single test for all known epilepsy-associated genetic mutations.

Treatment and management

Currently, no cure exists for epilepsy. However, a wide range of treatments are available that provide varying degrees of success in controlling the symptoms of epilepsy.

Medications

Medication is the most effective and widely used treatment for the symptoms of epilepsy. Most medications work by interfering with or stopping the abnormal electrical activity in nerve cells that cause seizures. This form of treatment is generally referred to as anticonvulsant therapy. Medication is considered effective if the patient is free of seizures for at least one year.

Anticonvulsants are powerful drugs that can produce a variety of side effects, including nausea, fatigue, dizziness, and weight change. They can also increase the risk of birth defects, especially involving the early stages of

KEY TERMS

Absence seizure—A type of epileptic seizure characterized by a brief loss of, and return to, consciousness, usually without being followed by a period of confusion or disorientation.

Aura—A disturbance in one or more of the five senses before the beginning of an epileptic seizure.

Congenital—Present at birth.

Convulsion—Involuntary contractions of body muscles that accompany a seizure episode.

De novo mutation—A mutation that arises in a child that is not present in either parent.

Eclampsia—The onset of seizures in a pregnant woman with pre-eclampsia, a condition characterized by protein in the urine, high blood pressure, and sometimes other organ dysfunction.

Idiopathic—Of unknown origin.

Ketogenic diet—A high-fat, low-carbohydrate diet used to treat epilepsy in children who do not respond to anticonvulsant medications.

Lesion—A defective or injured section or region of the brain (or other body organ).

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Mitochondrial genes—A group of 37 genes contained in the DNA of mitochondria (mDNA), the

energy-producing organelles in cells. In humans, mDNA is inherited solely from the mother.

Myoclonic epilepsy—Epilepsy characterized by sudden jerking or twitching in the arms, legs, or upper body.

Post-ictal—Referring to the period following an epileptic seizure and its alterations in consciousness.

Psychogenic non-epileptic seizure (PNES)—An event that resembles an epileptic seizure but lacks the electrical discharge associated with epilepsy. PNES is associated with psychiatric disorders, most often conversion disorder, and is often triggered by a psychological trauma of some kind.

Seizure—Any unusual body function or activity that is under the control of the nervous system.

Status epilepticus—A potentially life-threatening seizure that either lasts longer than five minutes or consists of two seizures within a five-minute period without the patient returning to normal consciousness between the seizures.

Sudden unexplained death in epilepsy (SUDEP)—A fatal complication of epilepsy that accounts for about 15% of deaths in epilepsy patients. It is thought to result from a combination of factors, including cardiac and respiratory as well as neurological factors.

embryonic development of the nervous system when taken during pregnancy.

Doctors prefer to put their patients on just one type of anticonvulsant drug. Some patients, however, experience more effective relief from their epilepsy symptoms by taking a combination of two different but complementary forms of medication. The choice of medication depends on the type of seizure that affects a patient and the patient's medical history—including response to other drug therapies—age, and gender. For example, the drug carbamazepine is one of the most effective medications and has little impact on important cognitive functions such as thinking, memory, and learning.

Newer medications generally produce fewer side effects than their predecessors. Research into gene therapy may ultimately be the most effective form of epilepsy treatment, but it is still in the very early stages.

Unfortunately, medication is ineffective for more than one-third of known cases of epilepsy. More than

30% of patients with epilepsy cannot achieve and/or maintain adequate control of their seizures. In addition, some genetic mutations may reduce the effectiveness of antiepileptic medications.

Surgery

Surgery is recommended for some patients for whom medication cannot effectively control the frequency or severity of their seizures. It is a treatment option only in extreme cases where doctors can identify the specific site in the brain where seizures originate. The most promising candidates for surgery are those with a single lesion on the temporal, frontal, or occipital lobes of the brain.

Prior to surgery, the patient must complete extensive testing to determine the precise patterns of seizures and to locate their point of origin in the brain. Patients spend extended stays in the hospital during which their seizures are recorded on video and with the aid of EEGs. This machine records patterns of electrical activity in the brain

QUESTIONS TO ASK YOUR DOCTOR

- I have been told that epilepsy runs in our family. What are the chances that my children will inherit this disorder?
- What is the cause of my child's epilepsy?
- What other individuals—family, friends, neighbors, school friends, or others—should we tell about our child's epilepsy?
- Should we consider brain surgery as a method for curing our child's epilepsy?

by using sensors (referred to as electrodes) attached to various parts of the body.

The surgical procedure involves the removal of a small part of brain tissue in the region suspected of being the origin of the seizures. The anterior temporal lobe and hippocampus are the most common areas in which tissue is removed. In some studies, more than 83% of patients were free of seizures following surgery, and 97% showed significant improvement in their condition.

Other therapies

Vagus nerve stimulation (VNS) is another form of treatment for some cases of epilepsy that are unresponsive (referred to as refractory epilepsy) to other forms of medical therapy. VNS may also be recommended for patients who cannot tolerate the side effects of medication. This procedure involves implanting a device that stimulates the vagus nerve, located in the left side of the neck. In one study, this treatment reduced seizures by 78%.

Deep brain stimulation (DBS) is another method approved for treatment of epilepsy by the Food and Drug Administration (FDA). DBS involves the implantation of electrodes in the brain, attached by wires to a battery-operated pulse generator implanted beneath the skin of the patient's abdomen or the skin over the area near the collarbone. DBS appears to be helpful in treating patients who do not respond to antiseizure medications.

In 2021, researchers reported successful treatment of drug-resistant epilepsy using a brain-computer interface (BCI), a communication system capable of converting neural activities into signals and providing real-time seizure detection and prediction as well as delivery of warning stimuli or therapies. The BCI not only continuously monitors the patient's brain waves for signals of an impending seizure, it automatically responds with electric

pulses that can prevent the seizure before it occurs. It also can trigger an implanted electrical neurostimulator to prevent, abort, and control seizures.

A special dietary program is another treatment option for patients who are not good candidates for surgery or those who have had little success with anticonvulsant medication. This form of treatment, called the ketogenic diet, can be effective for many types of epilepsy. It is most appropriate for young children, whose parents can follow the rigid requirements of the diet. Older children and adults tend to have greater difficulty in sticking to the dietary rules for an extended period of time. The ketogenic diet is a stringent diet that is very high in fat but low in proteins, carbohydrates, and calories. The excessive fat produces high levels of a substance called ketones (which the body makes when it breaks down fat for energy). Somehow, these ketones help to reduce the incidence of epileptic seizures. The success of this form of treatment varies. For some patients, the high-fat diet is the best form of treatment. For others, the diet is less effective.

Prognosis

As of 2021, there was no cure for epilepsy, but seizures can be effectively controlled in about 70% of patients. Patients with the poorest prognoses are those who have a large number of seizures in the first six months after the initial seizure; those who show little response to the initial course of therapy; those with generalized seizures; those with psychiatric problems; and those with family histories of epilepsy. Unfortunately, epilepsy can shorten a person's lifespan; patients with epilepsy have a risk of death between 1.6 and 4 times higher than that of the general population. The chief causes of death in epilepsy patients are suicide (four to six times more common in epilepsy patients than in the general population); trauma resulting from falls; status epilepticus (a condition in which seizures follow each other without recovery of consciousness in between); and sudden unexpected death in epilepsy, or SUDEP. About 15% of deaths of epilepsy patients are due to SUDEP.

Erythropoietic porphyria

Definition

Erythropoietic porphyria (EPP) is an inherited condition that leads to the build-up and heightened excretion of porphyrins or precursors to porphyrins. It is inherited in an autosomal recessive pattern, which means that both parents must transmit the disorder. Of all the porphyria conditions, this is the most disfiguring.

The disorder is also known as congenital erythropoietic porphyria (CEP), congenital porphyria, Gunther's disease, and Gunther porphyria.

Symptoms may be recognized in early infancy; however, they may be found as early as in utero or as late as adulthood.

Description

In erythropoietic porphyria, affected individuals suffer a deficiency in an enzyme needed to break down porphyrins; therefore, the substance accumulates in the blood. As the porphyrins accumulate, they cause major disruptions to the affected parts of the body, leading to enlargement of the liver or spleen and creating multiple types of anemia and other blood disorders.

Genetic profile

EPP can result from mutations in the ferrochelatase (*FECH*) and delta-aminolevulinic acid synthase-2 (*ALAS2*) genes. Disease that results from *ALAS2* gene mutations is less common and is called X-linked protoporphyria (XLP) instead of EPP.

The *FECH* mutation is inherited in an autosomal recessive manner, and it is common for the affected individual to inherit a severe mutation from one parent and a weak mutation from the other. Weak variants of *FECH* are common in Caucasians and rare in African American, Japanese, and Chinese populations. The weak variant is called a "hypomorphic" variant because it causes the production of a less-than-normal amount of ferrochelatase but will not cause EPP on its own.

KEY TERMS

Corneal—Pertaining to the cornea of the eye, which is the clear covering that protects the front of the eyeball.

Hygroma—A condition in which fluid builds up in a sac or cyst.

Photosensitivity—Abnormal sensitivity to light.

Porphyrin—An organic compound containing nitrogen.

Splenectomy—Removal of the spleen.

Thrombocytopenia—Abnormally low platelet levels in the blood.

Wood's light—An ultraviolet light used in medical settings because of its ability to create fluorescence in the presence of substances such as porphyrins.

The more severe mutation of *FECH* is expressed in all individuals with EPP. Carriers of this mutation are not affected as long as they do not also carry the weak variant at the other *FECH* locus. Carriers of the severe mutation will have some children with EPP if their partner is also a carrier for the weak or severe *FECH* gene mutation.

In XLP, mutations of the *ALAS2* gene are found on the X chromosome and cause increased synthesis of the enzyme ALAS2 in the bone marrow. This is considered a gain of function mutation and has been described in different XLP families. In XLP the overproduction of protoporphyrin exceeds necessary levels for the production of heme and hemoglobin. Like hemophilia and other X-linked genetic diseases, XLP is more common in men, because unlike women who have two X chromosomes, men only have one X chromosome and will be affected if they inherit an *ALAS2* mutation. Women with an *ALAS2* mutation will pass that mutation to half of their daughters, who will usually be carriers, and to half of their sons, who will be affected with XLP.

Demographics

Erythropoietic porphyria is very rare. As of 2021, only 150 cases had been reported worldwide.

Signs and symptoms

Causes

The cause of this disorder is genetic. It is necessary for both parents to carry the genetic material for the disease in order for an offspring to have it.

Symptoms

Symptoms are related to where the stores of excess porphyrins are located in the body. They may reside in plasma, red blood cells, urine, and feces. In infants, the condition may lead to red urine, and teeth may also take on a red stain. Blistering of the skin may occur.

EPP can cause photosensitivity; sun exposure to the skin may result in extreme reactions including severe blistering, scarring, pigment changes, skin infections, enlarged spleen (splenomegaly), and anemia. Secondary infections resulting from sun exposure may become so severe as to lead to amputation, particularly of the fingers, as well as portions of the ear, eyelids, and nose.

There is a literature report of a boy in Serbia who was diagnosed at age 16 after he exhibited red urine for a period of six months. A mild form of adult-onset erythropoietic porphyria has been described in medical literature, which included such symptoms as an enlarged spleen and hemolytic anemia, photosensitivity, and thrombocytopenia.

Erythropoietic porphyria also causes symptoms of the eye, including blepharitis, conjunctivitis, and loss of eyelashes and eyebrows. Corneal scarring may occur, sometimes leading to blindness.

Diagnosis

Examination

In newborns, photosensitivity may begin as early as the first few days of life. In diapers of infants with the disorder, urine and feces will contain pink areas when viewed under a Wood's light. The abundance of pink is indicative of urine and feces that have higher-than-normal levels of porphyrins.

The disorder may be diagnosed prior to birth and is one cause of fetal anemia, which requires transfusion. One report in the medical literature discusses cases in which diagnosis occurred during gestational weeks 14 and 19. The main diagnostic feature was the presence of cystic hygroma. By weeks 19 and 22, both fetuses developed nonimmune hydrops fetalis. They also showed intrauterine growth retardation, hyperechogenic bones and kidneys, and dark amniotic fluid due to the raised levels of porphyrins. German scientists identified four gene mutations: *C73R*, *-86A*, *G236V*, and *L237P*.

It is believed that cases that show symptoms later in life are less severe.

Tests

Amniocentesis, which may be performed at 16–18 weeks of pregnancy, may reveal the disorder because

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks of transfusion?
- What are the signs that transfusion is no longer effective?
- How will splenectomy help in my long-term prognosis?

uroporphyrinogen III cosynthetase is found in cultured amniotic cells and in genetic testing.

A Japanese study published in 2002 found that tears contain evidence of excess porphyrins. The scientists concluded that it was important to check for the presence of porphyrins in tears, as build-up of the substance in the eyes could lead to eye damage.

Treatment and management

Traditional

Therapies performed in this procedure include blood transfusion, splenectomy, and substances such as charcoal and cholestyramine, which bind the porphyrins and prevent their absorption. Bone marrow transplant has also been performed on patients with severe cases. Patients with an enlarged spleen may undergo surgical removal of that organ (splenectomy).

Because reactions to sun exposure may lead to serious consequences, avoiding the sun is essential.

Blood transfusions are used in more severe cases. In persons who have depended on repeated transfusions, bone marrow transplant may be considered. Researchers recommend that definitive diagnoses be made as early as possible so that bone marrow transplant may be considered earlier in the course of the disorder.

Treatment has also been accomplished with hydroxyurea; however, long-term use may result in untoward side effects that may involve the eye.

Drugs

Steroids may be given to reduce the size of the spleen if it is enlarged.

Prevention

Erythropoietic porphyria cannot be prevented; however, medical procedures such as transfusion and splenectomy may prevent serious complications. Because the disorder requires gene mutations from both parents, genetic counseling is recommended.

Prognosis

Prognosis depends on the severity of the disorder in a particular person and its response to treatments such as splenectomy and transfusion. Transfusion becomes less effective during puberty. Bone marrow transplant has achieved longer-term success.

Prognosis is usually better for those with the adult-onset form of the disease, which tends to be milder. Prognosis also depends on eye involvement, as complications such as corneal scarring may lead to blindness.

Erythropoietic protoporphyria

Definition

Erythropoietic protoporphyria, which is an inherited disorder, was identified as a clinical syndrome in 1961. Individuals with this disorder have a significant increase

KEY TERMS

Enzyme—Substance in the body that causes a reaction to occur.

Photosensitivity—Abnormal sensitivity to sunlight.

in protoporphyrin, a substance involved in making a component of red blood cells. The classic symptom is severe photosensitivity.

Description

In erythropoietic protoporphyria, protoporphyrin accumulates in bone marrow, red blood cells, plasma (liquid portion of the blood), skin, and the liver. The accumulation of this material creates severe sensitivity to sunlight as well as damage to the liver.

The normal erythrocyte level of protoporphyrin is 60 microg/dl of red blood cells. Persons with erythropoietic protoporphyria may have levels of protoporphyrin as high as 1,000 microg/dl of red blood cells.

Exposure to sunlight makes active the protoporphyrin molecules, which leads to destruction of nearby tissue. Protoporphyrins that accumulate in the liver can lead to bile stones. When the substance accumulates in the liver, it can lead to damage to that organ.

A study published in 2013 reported the cause of one patient's mutation to be from a substitution of nucleotide thymine for nucleotide cytosine, causing the malformation of the *FECH* gene and ultimately resulting in this blood disorder.

A person with this syndrome is at risk for severe liver damage, possibly requiring a transplant.

Genetic profile

This syndrome is rare, possibly because the set of circumstances required for its presence is complex. While some researchers have found evidence of dominant inheritance (from one parent), others have found that the disorder is autosomal recessive (present in both parents). The most recent understanding is that the mutant gene is inherited from one parent, while the other parent has low activity of the enzyme ferrochelatase.

Demographics

The disorder has not been found in persons of African descent.

Signs and symptoms

Erythropoietic protoporphyria is an inherited disorder. Symptoms arise because of the accumulation of a substance called protoporphyrin. The chief cause of the build-up of this material is a deficiency in ferrochelatase, which is an enzyme. The classic symptom, which often begins during childhood, is severe sensitivity to light, or photosensitivity.

Sensitivity is so severe that it includes long-wavelength ultraviolet light, which reaches the person through window panes. Very soon after exposure to sunlight, persons experience severe skin pain and swelling because the molecules of protoporphyrin are activated by natural light.

Protoporphyrin accumulates in the bone marrow, red blood cells, plasma, skin, and ultimately in the liver. In addition to the cutaneous symptoms, affected individuals may develop bile stones and disorders of the liver such as pain in the abdomen and jaundice, as well as an enlarged spleen. Studies have also shown malabsorption of iron leading to anemia.

Diagnosis

Examination

Erythropoietic protoporphyria is most often diagnosed during childhood, usually by the time the child reaches ten years of age. Cases of adult-onset disease have been reported, but they are less common. The classic symptom is swelling and severe skin pain following exposure to the sun. Physicians may not recognize the disorder because the child does not have any blistering or scarring from the damage.

Tests

Prenatal and postnatal tests are currently available to diagnose an individual suspected of having erythropoietic protoporphyria. A molecular genetic test can be performed for the *FECH* gene, which is the gene that codes for the enzyme ferrochelatase. A mutation of this gene will show within the DNA analysis targeted on the erythropoietic protoporphyria panel. This particular test, either prenatally using chorionic villi, amniotic fluid and cultured cells or postnatally using whole blood, is more than 98% accurate for identifying mutations.

Treatment and management

Traditional

Persons with erythropoietic protoporphyria are instructed to avoid sunlight. In fact, avoiding sunlight is

QUESTIONS TO ASK YOUR DOCTOR

- How effective is the application of sunblock?
- What distance away from a window should I stay on a sunny day?
- How often should my liver function be monitored?

the foundation for avoiding a severe reaction. If a person is exposed, treatment is the same as that given for sunburn.

If gallstones develop, persons with this disorder need to have them surgically removed.

Drugs

Beta-carotene, which will cause the skin to become more yellow if taken in sufficient doses, may be taken as a treatment. This substance offers the skin a level of sun protection; however, affected individuals are still instructed to avoid sunlight. It is important that the beta-carotene used is pharmaceutical grade. A popular brand is Lumitene, which is given to children under age 14 years in doses ranging from 30 to 150 mg per day. The adult dose normally ranges from 30 to 300 mg per day. The dose is usually adjusted according to the severity of the person's symptoms as well as his or her tolerance to beta-carotene. Concern has been reported for the use of synthetic beta-carotene supplements in smokers due to a potential association with lung cancer.

A study reported in 2009 found improvement in photosensitivity in five patients treated with afamelanotide, a hormone that enhances formation of melanin, which is a pigment in the skin. These five patients showed improved ability to withstand artificial light; they also experienced an increase in melanin density after four months.

A 2013 study reported improvement of symptoms via low doses of intravenous iron therapy in a 23-year-old Caucasian male heterozygous for the disorder.

Liver disease associated with this disorder is sometimes treated with cholestyramine.

Prevention

Erythropoietic protoporphyria cannot be prevented; however, a 2014 study revealed that antisense oligonucleotide-based therapy can improve the condition of individuals with the disorder by increasing the production

of the wild type FECH mRNA that codes for the protein necessary for the correct levels of protoporphyrin.

Symptoms may also be alleviated by refraining from exposure to sunlight. The potential for serious liver damage should be monitored through yearly blood workups.

It is recommended that persons with the disorder wear medic alert bracelets so that in the event of a medical emergency, emergency personnel will understand that these individuals must not be exposed to bright light such as that found in an operating room. The information will also convey to medical personnel the need to avoid certain medications that may impact the liver.

Clothing should cover as much of the body as possible. Long sleeves and long pants or skirts are recommended. Protective films should be placed on windows, including those in the car. The usual sunscreens are not effective in persons with this disorder. Semi-opaque sunscreens, such as those with zinc oxide, that create a physical barrier may offer some degree of protection; however, persons with the disorder are advised to stay out of sunlight. Artificial light may also cause symptoms.

Prognosis

In most cases, persons with erythropoietic protoporphyria experience reactions to sunlight without other symptoms. However, some individuals develop liver damage, which may be fatal. Gallstones have been reported, even in younger patients. When these appear, they are surgically removed.

Persons who have erythropoietic protoporphyria syndrome are instructed to have yearly blood tests to measure the build-up of porphyrin in the red blood cells. They must also have liver function tests (blood tests) yearly, as well as urine and fecal testing.

In severe cases, affected individuals may require a liver transplant.

Essential hypertension

Definition

Essential or primary hypertension, the most common form of hypertension, is elevated blood pressure that develops without apparent cause. Genetic factors, however, appear to play a role in increasing the risk of developing the disorder.

Normal blood pressure refers to a range of values rather than a specific set of numbers and varies with factors such as age, race, and gender. A blood pressure reading greater than 140/90 mm Hg (millimeters of mercury pressure) is generally considered to be elevated. In this measurement, 140 refers to the systolic pressure (the maximum pressure in the arteries when the heart contracts). The 90 refers to the diastolic pressure (the lowest pressure in the arteries when the heart is relaxed between contractions).

Description

More than 95% of all elevated blood pressure can be classified as essential hypertension. When a disease, other physical problems, medications, or even temporary physical exertion or stress causes high blood pressure, the condition is called secondary hypertension.

Blood pressure refers to the force exerted by blood against the interior walls of the body's blood vessels. There are three categories of blood pressure corresponding to the three types of blood vessels: arterial, capillary,

and venous. In individuals with hypertension, arterial pressure (recorded as two numbers: systolic and diastolic pressure) is the most important measurement to obtain. The reason is that because of their relative proximity to blood flowing forcefully from the heart, arteries must withstand the highest pressures of all the body's blood vessels.

The body requires a relatively constant blood pressure level to ensure adequate passage of nutrients and oxygen to organs and tissues. To maintain a constant level of pressure, the body must balance and respond to a number of factors such as:

- volume of blood in the circulatory system
- amount of blood ejected by the heart (stroke volume)
- heart rate
- thickness of the blood (viscosity)
- elasticity of the arteries

When the systolic or diastolic pressure is elevated for an extended period of time, such as months or years, the heart has to work harder and may become damaged, along with the blood vessels. If it remains untreated, high blood pressure can lead to a variety of serious health problems, including heart disease, stroke, and kidney failure.

Genetic profile

Studies suggest that some people with essential hypertension may inherit abnormalities of the sympathetic nervous system—the part of the nervous system that controls heart rate, blood pressure, and the diameter of blood vessels. It is estimated that the risk of developing essential hypertension is increased two- to fourfold if one or both parents are diagnosed with the disorder.

Researchers have identified the chromosomes (11 and 18) that house the genes responsible for blood pressure regulation, although narrowing down the range of specific genes involved in hypertension is more difficult.

Genes under intense study are those that regulate a group of hormones known as the angiotensin-renin-aldosterone system. This system influences all aspects of blood pressure control, including blood vessel contraction, sodium and water balance, and cell development in the heart.

When blood pressure drops, the kidneys release an enzyme called renin, which initiates a chain reaction to bring blood pressure back up. Renin acts on angiotensinogen (a plasma protein) to produce the hormone angiotensin I (an inactive form), which is then converted to angiotensin II (an active form of the hormone) by the angiotensin-converting enzyme (ACE). Angiotensin II then stimulates the adrenal glands to release the hormone

KEY TERMS

Angiotensinogen—A plasma globulin (protein) formed in the liver and directly involved in the regulation of blood pressure.

Diastolic blood pressure—Blood pressure measured when the heart is resting between beats.

Renin—An enzyme produced by the kidneys.

Sphygmomanometer—An inflatable cuff used to measure blood pressure.

Systolic blood pressure—Blood pressure measured when the heart contracts (beats).

Vasodilator—Any drug that relaxes blood vessel walls.

aldosterone, which decreases kidney sodium excretion, thereby causing blood vessels to constrict and resulting in fluid retention and an increase in blood pressure.

Researchers believe that this angiotensin-renin-aldosterone system evolved millions of years ago to protect humans. By retaining salt and water and narrowing blood vessels, the body was ensured an adequate blood flow and the ability to repair injured tissue. Over time, however, this system outlived its original protective function and led to serious health complications.

Demographics

It is estimated that one in three Americans have high blood pressure; it is also estimated that one in five people who have high blood pressure are unaware of the problem. Also, hypertension is much more common among Caucasians than among Hispanics. Low levels of nitric oxide, which has been observed in individuals—particularly African Americans—with elevated blood pressure may be an important factor in the development of essential hypertension.

The prevalence of essential hypertension increases with age until at least the age of 80. Statistics indicate that more than half of all Americans over the age of 65 have hypertension. In those under the age of 55, essential hypertension is more common in males than in females. Over age 75, the rate is higher for women (78%) than for men (67%).

Signs and symptoms

People with essential hypertension may go years without showing symptoms. For this reason, high blood pressure is often called the “silent killer.” The first

symptom may be a heart attack or stroke. However, many people with hypertension may experience one or more of the following symptoms:

- headache
- dizziness
- blurred vision
- irregular or rapid heartbeat
- nosebleeds
- fatigue

Diagnosis

Although genetic studies hold hope for detecting, evaluating, and treating hypertension in the future, there are no reliable genetic screening tests for the disorder. Thus, essential hypertension is a condition that cannot be diagnosed until it has developed; it is often diagnosed during a routine physical or medical examination.

Blood pressure is measured by an instrument called a sphygmomanometer. A cloth-covered rubber cuff is wrapped around the upper arm and inflated. When the cuff is inflated, an artery in the arm is squeezed to momentarily stop the flow of blood. Then the air is let out of the cuff while a stethoscope placed over the artery is used to detect the sound of the blood spurting back through the artery. This first sound is the systolic pressure. The last sound heard as the rest of the air is released is the diastolic pressure. Both sounds are recorded on the mercury gauge of the sphygmomanometer.

Because a number of factors such as pain, stress, or anxiety can cause a temporary increase in blood pressure, hypertension is not diagnosed on the basis of one elevated reading. Also, blood pressure results may be different depending on which arm is used. Thus, if a blood pressure reading is 140/90 or higher for the first time, the physician will have the individual return for another blood pressure check. Diagnosis of essential hypertension is usually made based on two or more readings after the first visit.

A typical physical examination to evaluate hypertension includes:

- medical and family history (especially important to determine a genetic contribution)
- physical examination
- examination of the blood vessels in the eye
- chest x-ray
- electrocardiograph (EKG)
- blood and urine tests

QUESTIONS TO ASK YOUR DOCTOR

- What blood pressure range is suggestive of hypertension in my child?
- How can we tell if his hypertension is a result of genetic or environmental factors?
- Are there treatments for hypertension caused by genetic factors and, if so, what are they?
- What steps can we take to help keep my child's blood pressure under control?

Treatment and management

There is no complete cure for essential hypertension because unlike secondary hypertension, there is no single cause of the problem; it is a complex disorder only determined in part by genes. Environmental (lifestyle) factors interact with genetic factors to produce hypertension.

Essential hypertension can be treated and managed effectively even if an individual has a genetic predisposition to the disorder. If essential hypertension is mildly or even moderately high, it may be possible to bring it down to a normal level without medication. Weight loss, changes in diet, and exercise may be the only treatment necessary. General nonpharmacologic recommendations include:

- reducing the amount of salt (sodium) and fat in the diet
- exercising regularly
- maintaining a healthy weight
- limiting alcohol and caffeine consumption
- quitting smoking
- reducing stress through stress management techniques, relaxation exercises, or counseling

If lifestyle changes are not effective in lowering blood pressure to a normal level, medication may be prescribed. There are many types of drugs available to treat essential hypertension. The main categories of drugs include:

- diuretics (help kidneys eliminate excess salt and water from the body's tissues and blood, thereby reducing swelling and lowering blood pressure)
- beta-blockers, alpha-blockers, and alpha/beta blockers (act on nervous system to slow heart rate and reduce the force of the heart's contractions)
- angiotensin-converting enzyme (ACE) inhibitors (block the production of substances that constrict blood vessels and reduce salt and water buildup in the tissues)

- calcium channel blockers (block the entry of calcium into muscle cells in artery walls, making arteries more relaxed)
- vasodilators (relax artery walls and lower blood pressure rapidly)
- peripheral-acting adrenergic antagonists (act off nervous system to relax arteries and reduce the force of the heart's contractions)
- centrally acting agonists (act on nervous system to relax arteries)

When a blood pressure medication is prescribed, it is important to:

- take the medication regularly, exactly as prescribed
- report any side effects immediately
- have regular follow-up visits with a physician

It may take weeks or even months to find the most effective pharmacologic treatment. Once an effective drug or combination of drugs is found, individuals with high blood pressure may require treatment for the rest of their lives.

Prognosis

The higher the blood pressure, the worse the prognosis generally is. However, most serious complications of essential hypertension can be delayed or even avoided by receiving regular blood pressure checks, and by treating the disorder as soon as it is diagnosed.

Essential tremor

Definition

“Tremor” is derived from the Latin term meaning “to shake.” It is an involuntary rhythmic back-and-forth shaking of a part of the body, resulting from alternating or irregular contractions of muscles. Essential tremor (ET) is the most common movement disorder. It is a syndrome characterized by a slowly progressive tremor of certain body parts, most commonly the arms, hands, and head, when the respective body part is maintained in a constant position.

Description

James Parkinson in 1817 was the first to describe and differentiate ET from the tremor seen in Parkinson’s disease. ET is also called benign essential tremor or familial tremor. ET is called benign since it does not increase an individual’s risk of mortality, and it is called essential since the cause was initially unknown. Several gene mutations that cause ET have now been identified.

ET is caused by abnormal communication between certain areas of the brain, including the cerebellum, thalamus, and brain stem. In most cases, the tremor is mild and nonprogressive; however, a few people with ET have a slowly progressive form with the tremor eventually involving the voice box, tongue, legs, and trunk. ET can be quite disabling if the tremor is severe and widespread, and it can substantially affect a person’s quality of life.

Genetic profile

ET can occur either as a random form called sporadic or more commonly, as an autosomal dominant inheritance form with variable penetrance. In autosomal dominant inheritance, an individual only needs one mutated gene to develop the condition, and if the condition has variable penetrance, only some descendants may develop it.

Some cases of ET appear to be sporadic, but this could be due to the fact that in certain families all

individuals who inherit the gene do not show symptoms. In familial ET, 50% of patients develop symptoms by 40 years of age, while sporadic ET has a later age of onset.

Most studies indicate that 50%–70% of ET is familial. First-degree relatives are five times more likely to develop ET than a person without an affected relative. Children of affected individuals have a 50% risk of inheriting the gene, and expression of this is nearly complete by 70 years of age. It is unclear as of 2021 whether the symptoms of familial ET begin earlier with each successive generation, a process called anticipation.

Several susceptibility genes have been identified in ET. One is a familial essential tremor gene called *ETM1* or *FET1*, found on the long arm of chromosome 3. Another is *ETM2* on the short arm of chromosome 2. A third mutation in chromosome 4p may also cause postural tremor. A mutation of chromosome 6p23 has also been linked to a few cases of ET, as has a mutation in *LINGO1* (leucine-rich repeat and Ig-containing domain 1) variant rs9652490.

Demographics

ET is one of the most common neurologic movement disorders of adults. It affects about 10 million people in the United States alone, and it is more prevalent than Parkinson’s disease or Alzheimer’s disease. The incidence of ET has two distinct ages of onset: one occurs in individuals in their early 20s, and the second involves adults in their 60s. ET can occur in children, although onset is rare before age ten. There is no major ethnic or gender difference, although males tend to have more severe tremor in the arms or legs and females have more severe head tremor.

Signs and symptoms

Tremor is usually the only symptom seen in ET, although there is some data to suggest that additional symptoms may include changes in cognition, personality, mood, and hearing.

There are three types of tremor that can be observed in ET: postural tremor, kinetic tremor, and internal tremor. The most common tremor of ET is a postural tremor, seen when the patient is voluntarily maintaining a fixed antigravity position of a limb or holding outstretched hands. This resembles a physiologic tremor that is present in everyone but is more severe in an affected individual. Postural tremor usually begins in both hands simultaneously, but 10%–15% of patients notice tremor onset in the dominant hand. Tremor usually moves from the hands to the arms over time. Initially the tremor may be noticeable only during periods of fatigue or anxiety,

but it becomes more constant over time. The severity of tremor varies considerably even from day to day. Tremor worsens with emotion, cold, hunger, and fatigue and tends to increase with age. It can range from being mild and a minor annoyance in one individual to severe and disabling in another family member.

Some patients have worsening of tremor while performing goal-directed tasks, such as writing, buttoning a shirt, or drinking from a cup. This is called intention or kinetic tremor. This type of tremor is worse than a positional tremor and is the major cause of disability.

The third type of tremor is internal tremor, which is a feeling of general shakiness or a sensation of vibration inside the body.

In about 30% of patients, the tremor involves the head region. Head tremor (titubation) is the second most common body part to be affected and can occur either in isolation or with hand tremors. Head tremor is in mostly a horizontal sideways pattern, as if indicating no. Voice and tongue tremor causes dysarthria (difficulty in articulating words) and quavering or shaky speech, and it is usually seen with advancing age above 65. Tremor generally disappears during sleep and is minimal during periods of rest.

Memory, intellect, strength, and muscle tone remain intact. Some associated symptoms like ataxia (unsteady and uncoordinated gait) and dystonia (repetitive movements and abnormal postures) can also be seen.

Diagnosis

Although ET is a common condition seen in general medical practice, diagnosis may be difficult and treatment challenging. It is best diagnosed and treated by a neurologist or a physician trained in movement disorders. No biomarkers, blood tests, or imaging tools are available to assist in diagnosis. Thyroid disease, excess caffeine consumption, and medication side effects should be excluded, as these can mimic ET. Magnetic resonance imaging scans are used only to exclude other causes of tremor, such as multiple sclerosis.

Diagnosis is mainly clinical and depends on recognizing the postural tremor, absence of rest tremor that is seen in Parkinson's disease, presence of tremor for more than three years, a decrease in tremor with alcohol consumption, and a family history of similar tremor. Clinical tremor questionnaires and rating scales can be helpful in the diagnosis and in assessing response to treatment. During the neurological assessment, the physician may use simple tests like spiral or line drawing, handwriting, tasks such as taking a water-filled cup to the mouth, articulating vowels, and so on, to determine the extent and

severity of ET. An accelerometer is a simple device attached to the fingers that measures tremor frequency.

Exclusion criteria for ET include the following symptoms:

- prominent dystonia
- known causes of enhanced physiologic tremor
- psychogenic origin of primary orthostatic tremor
- isolated voice tremor
- isolated position or task-specific tremor
- isolated tongue or chin tremor
- isolated leg tremor

Treatment and management

Treatment is based on how disabling the symptoms are to the patient, since early treatment has not been shown to stop or delay the disease progression. There is a 50% chance that the tremor will respond to currently available medications without undue side effects. Sometimes trials with multiple medications may have to be done before the tremor responds. Depending on coexisting medical conditions and neurological diseases, treatment must be individualized.

Lifestyle changes, including elimination of caffeinated foods like sodas, coffee, and chocolates, and other stimulants like cigarettes, are the first step in treatment. Biofeedback, acupuncture, yoga, tai-chi, and guided imagery are techniques that can be used in patients in whom the tremor worsens with stress and anxiety. In 50% of patients, alcohol may reduce tremor for up to two hours, but this is not to be considered therapy. Excessive alcohol consumption can worsen tremor as a rebound phenomenon.

Adaptive devices like wrist weights and plate guards can help to minimize tremor and interference with daily activities. Specially designed utensils (such as rocker knives and utensils with large handles) and electrical appliances (such as can openers and toothbrushes) can make daily activities easier. Certain simple precautions can enable many people to continue their normal daily activities. For example, objects should be grasped firmly but comfortably and held close to the body. Cylinders of foam can be placed around handles to make them easier to hold. Other helpful measures include using straws, button hooks, Velcro fasteners, zipper pulls, and shoe horns. Counseling may be needed to help patients deal with social isolation resulting from severe tremor.

The most commonly used medication to treat ET is propranolol, which is a beta-blocker. It prevents the action of adrenaline and reduces tremor amplitude. It is available in a short- and long-acting form. The effect of

KEY TERMS

Acupuncture—An alternative health procedure based on ancient Chinese methods, involving insertion of thin needles at specific pressure points in the body.

Alzheimer's disease—A neurodegenerative disease marked by the loss of cognitive ability, generally over a period of 10–15 years, associated with the development of abnormal tissues and protein deposits in the brain.

Anticipation—The apparent tendency of certain diseases to appear at earlier ages and with increasing severity in successive generations.

Ataxia—A condition of bodily incoordination and unsteadiness that is most often caused by disease activity in the cerebellum.

Autosomal dominant—A type of genetic inheritance in which a trait (or a disease) is produced even when only one copy of an abnormal gene is present.

Biofeedback—A technique in which patients are trained to gain some voluntary control over certain physiological conditions, such as blood pressure and muscle tension, and to promote relaxation.

Cerebellum—The lower back part of the brain responsible for functions such as maintaining balance and coordinating and controlling voluntary muscle movement.

Computed tomography (CT)—A special radiographic technique to visualize internal organs using a computer to combine multiple x-ray images into a two-dimensional cross-sectional image.

Dysarthria—Refers to a group of speech disorders caused by disturbances in the strength or coordination of the muscles of the speech mechanism as a result of damage to the brain or nerves.

Dystonia—A movement disorder involving prolonged muscle contractions that cause twisting and repetitive movements or abnormal posture.

Functional magnetic resonance imaging (fMRI)—A form of imaging of the brain that registers blood flow to functioning areas of the brain.

Gamma amino butyric acid (GABA)—An amino acid that functions as the major inhibitory neurotransmitter in the nervous system.

Gamma knife—Equipment that precisely delivers a concentrated dose of radiation to a predetermined target using gamma rays.

Globus pallidus—A small paired structure present in the deep portion of the brain in front of the brain stem that is considered a part of the basal ganglia and helps in movement control.

Inferior olivary nucleus—A small collection of cells seen in the lower part of the brain stem, which has connections to the cerebellum and is involved in control of movements.

Magnetic resonance imaging (MRI)—An imaging technique that uses the properties of magnetism to create nondestructive, three-dimensional, internal images of the soft tissues of the body, including the brain, spinal cord, and muscle.

Multiple sclerosis—A progressive autoimmune disease in which the body attacks its own central nervous system, gradually destroying the white fatty substance that surrounds nerve fibers, thereby damaging sites in the brain and spinal cord.

Orthostatic—Posture that is maintained while standing.

Parkinson's disease—A progressive disease occurring most often after the age of 50, associated with the destruction of brain cells that produce dopamine and characterized by tremor, slowing of movement, and gait difficulty.

Penetrance—The extent to which a disease expresses itself in individuals that have the mutation; for example, if all individuals with the abnormal gene exhibit the disease, the disease is said to have complete penetrance.

Positron emission tomography (PET)—A form of nuclear medicine scanning that measures brain activity using low doses of a radioactive substance.

Red nucleus—A small structure present in the brain stem that is involved in the control of movement.

Sporadic—Disease that is apparently not hereditary.

Tai-chi—A Chinese system of physical exercises that uses slow, smooth body movements to help with posture control and relaxation.

Thalamus—A pair of large egg-shaped structures near the brain stem that act as the main sensory relay station and help with control of movement.

Titubation—Tremor of the head.

Yoga—An exercise that combines relaxation and breathing techniques to combat stress and help circulation and movement of the joints; yoga has its origin in ancient Indian medicine.

QUESTIONS TO ASK YOUR DOCTOR

- What is the long-term effect of essential tremor?
- What special care does a person with essential tremor require?
- What other healthcare professionals should I consult?
- Are there organizations or support groups where I can talk to other people who have essential tremor?
- Do you have information I can take home?

the short-acting form lasts for three to four hours and is suitable for taking prior to a specific task, such as giving a speech or attending a social gathering. It is rare for the tremor to completely disappear with treatment, but about 60% of patients respond to it. The medication works best for hand tremor. Side effects include lowering of blood pressure and heart rate, aggravation of asthma, depression, fatigue, and impotence. Primidone is a barbiturate and is the second most commonly used medication. It was originally developed as an antiseizure medication and is taken once a day at night in order to minimize the side effects of drowsiness and fatigue. It can be used for long periods of time with minimal side effects. Other medication treatments include gabapentin and benzodiazepines like diazepam and clonazepam. A combination of propranolol and primidone can be used in resistant cases. Newer therapeutic approaches include botulinum toxin injection into the muscles, such as neck muscles, to treat head tremor. Transient weakness may be experienced, but the therapeutic effect lasts for three to six months.

Invasive surgical intervention is usually reserved for patients with severe disabling unilateral tremor, bilateral tremor, head and voice tremor, functional disability that interferes with the activities of daily living, or tremor that is unresponsive to the highest tolerated doses of medications.

The thalamus is a paired structure deep inside the brain. It is intimately involved in movement regulation. In thalamotomy, a small pea-sized hole is made in the thalamus on the side opposite to the tremor to disrupt faulty circuits. Because the thalamus is close to vital brain stem structures, the surgery has to be done only by an experienced neurosurgeon. Postoperatively, some temporary side effects like confusion, weakness, and speech difficulty may occur. Bilateral thalamotomy is not advised, as it may cause loss of speech and other

permanent neurologic problems. Thalamotomy is especially helpful in patients with severe unilateral hand, arm, and leg tremor and is effective in up to 80% of patients. In a similar method using gamma knife, a small burn is made in the thalamus without a hole or operation being necessary.

Thalamic stimulation, or deep brain stimulation (DBS), is an alternative to thalamotomy. DBS involves implanting an electrode (a fine wire) deep in the center of the thalamus. The electrode is connected to a stimulation device (implantation pulse generator) similar to a pacemaker that is placed under the skin below the collarbone. By sending painless, high-frequency electrical currents through the electrode, it interrupts communication between tremor cells and helps the thalamus rebalance the tremor control messages. Patients may turn the pulse generator on and off by passing a hand-held magnet over the device. The batteries that power the pulse generator need to be surgically replaced every three to five years. Tremor reduction occurs within seconds of activation and can be quite dramatic. Significant or complete tremor reduction occurs in approximately 80% of people with this procedure, and efficacy has continued for six to seven years. The main advantages of this procedure are that implantation on both sides of the brain is possible, the device can be adjusted for optimal effect, and the device may be removed if desired. Other potential targets for DBS in ET include globus pallidus and subthalamic nucleus.

Prognosis

ET does not increase a person's risk of mortality, but it can result in varying levels of functional difficulty and disability depending on how severe the tremor is. With advancing age, the amplitude of the tremor worsens, and it is this feature that results in major disability. The patient with ET is disabled either due to physical limitations or from the resulting social embarrassment, which can lead to social withdrawal and depression. Everyday tasks that need fine motor skills and manipulation become difficult, such as writing, using utensils, drinking from a glass, or applying makeup. Patients may opt for early retirement or change jobs due to the severity of tremor.

Ex vivo lentiviral gene therapies

Definition

Ex vivo lentiviral gene therapy is a method of inserting, modifying, or removing bits of genetic material in an organism by using a virus from the lentiviral family. Ex vivo means that the genetic material is added to cells outside of the body and then introduced back into the body. Lentiviruses infect an organism by inserting DNA into the host cell's DNA. Ex vivo lentiviral gene therapy is often used to treat a disease by correcting problems in the genome.

Description**History**

The idea of gene therapy was first introduced in the late 1970s, but it was not until 1990 that the first successful human gene therapy trial occurred. A four-year-old girl named Ashanthi DeSilva was treated for adenosine deaminase deficiency (ADA). ADA is a severe and rare genetic disease that makes the immune

system unable to fight off infections from bacteria and viruses. This condition is often lethal, and patients need to largely stay at home because of their increased risk of infection.

Ashanthi had a variant in each copy of the gene that produces the protein adenosine deaminase. As a result, her body could not produce adenosine deaminase, which is required for a normally functioning immune system. During the procedure, some of Ashanthi's cells were removed. A virus called an adenovirus was used to insert a normal copy of the gene that produces adenosine deaminase into these cells. The cells containing the normal gene were then transfused back into her body.

The gene therapy was very successful and had no significant side effects. Ashanthi has since married and works to help other people with genetic conditions. This therapy was groundbreaking and led to the birth of a new field.

Unfortunately, there were problems with later clinical trials. Five of twenty participants with a similar immune deficiency disease who underwent gene therapy developed cancer. The virus that delivered the normal gene to the participants' cells turned on a cancer-causing gene. In 1999, during another trial using an adenovirus, a participant who was being treated for another disease died from an immune reaction. These trials resulted in a pause of gene therapy clinical trials for about ten years.

Gene therapy gradually rebounded, and in 2003, China became the first nation to approve it for clinical use as treatment for head and neck cancer. In 2017, the FDA approved two gene therapies in the United States. Since then, gene therapy has experienced a boom, and the FDA expects to approve 10 to 20 gene therapies every year by 2025.

In 2021, a gene therapy trial using a lentiviral by Bluebird Bio was halted because two patients developed cancer. It is not yet known whether the therapy itself caused the cancer.

Lentiviral and other viral vectors

One key requirement for gene therapy is a vehicle that can deliver the genetic material to the target cells. These vehicles, also called vectors, can be viruses or non-viral. The first vector used was an adenovirus. This virus was first isolated from human tissue in 1953. Usually, this virus does not cause serious symptoms in healthy people, but it can cause serious symptoms in people who have weak immune systems. The advantage of the adenovirus is that it does not integrate into the host's DNA, which can sometimes cause problems.

Ex vivo gene therapy. (Shutterstock/Art of Science)

In 1996, lentivirus vectors based on the HIV virus were developed for use in gene therapy. Lentiviruses are retroviruses. Retroviruses make a DNA copy of their RNA and insert it into the cells of their hosts. Lentivirus vectors are used in both gene therapy and cellular therapy. Cellular therapy involves transferring whole cells into a host. Lentiviruses vectors used in gene therapy are designed so that the virus does not replicate and cause an infection.

Use of lentiviral vectors

Gene therapy was initially designed to treat diseases that are caused by a variant in a single gene, like cystic fibrosis. It is now being investigated as treatment for cancers, autoimmune diseases like arthritis, and infectious diseases.

Gene therapy can be somatic or germline. Somatic gene therapy involves adding, removing, or changing the genetic material in tissue or cells, which results in the production of a naturally occurring protein that is lacking or not functioning correctly in an individual patient. Germline gene therapy adds, removes, or changes the genetic material in reproductive cells, or embryos, to correct genetic defects that could be passed on to future generations. Germline gene therapy is currently prohibited in the United States.

Gene therapy using lentivirus vectors has been used in clinical trials to treat immune diseases, inherited genetic diseases, and cancer. For example, lentiviral vectors have been used to change cells so that they are more receptive to cancer chemotherapies. The first cellular therapy using a lentivirus vector was approved in 2017 for the treatment of leukemia.

Lentiviral vectors have also been used to transport tools for editing genes, such as in CRISPR/Cas, which is a tool derived from the immune system of bacteria that can be used in gene therapy. CRISPR/Cas can be used to change an organism's DNA by making a cut in the DNA at a specific location and tricking the body's DNA repair mechanism to make the desired change.

These vectors have also been used in research to change the amount or stop the production of protein produced by a gene. This can be used to help study the function of different genes. In the future, it may also be used to treat disease.

Lentiviral vectors which do not integrate into the host genome (NILVs) are being researched. Research has been done on the use of NILVs in vaccines against infectious diseases and cancer. They have been successful in trials performed on animals. Further research needs to be done to see whether they will work safely on humans.

KEY TERMS

Cell—A building block that provides structure to the body and performs all of its functions. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle and connective tissue.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

Ex vivo—Referring to a procedure that takes place outside a living organism.

Gene—A sequence of bases in a DNA sequence that contains the instructions for a protein.

Genome—The complete set of genetic instructions of an organism.

Host—The body that the virus vector is infecting.

In vivo—Referring to a procedure that takes place within a living organism.

Pathogenic variant (mutation)—Any change in the sequence of a genome that causes disease.

Protein—Responsible for the structure and all of the functions of the body and cells.

RNA (ribonucleic acid)—The genetic material that is involved in creating proteins.

Tissue—Made up of cells that have a common function. The four types of tissue are: connective, epithelial (skin), muscle, and nervous tissue.

Variant—Change in the sequence of a genome.

Vector—A viral or non-viral vehicle that delivers the genetic material.

Advantages of lentiviral vectors

There are many advantages for using lentivirus vectors in gene therapy, including:

- They can provide long-term treatment.
- They can insert large genes into the DNA of the host.
- It is relatively easy to grow large amounts of the virus.
- They are effective in infecting the host.
- They can even be used for cells that are not dividing like nerve cells.
- Lentiviral vectors can fix more than one gene at a time.
- They can be used for gene therapy that directly injects the viral vector into a living organism.

QUESTIONS TO ASK YOUR DOCTOR

- Would gene therapy help my condition?
- Are there any gene therapies available that my child would qualify for?
- What risks can I expect with this type of gene therapy?

Disadvantages of lentiviral vectors

Although there are advantages to using lentiviral vectors, there are also many safety issues associated with the use of viral vectors. One of the biggest potential problems is that the lentivirus might insert DNA into other unintended region of the host's DNA which can cause problems. For example, it could insert DNA into a cancer-causing gene, resulting in a mutation and an increased risk of cancer. In some cases, it could result in mutations that can get passed down to future generations. Lentiviral vectors are a little less likely than other retrovirus vectors to cause unintended mutations.

Some other potential problems with lentiviral vectors are:

- Lentivirus vectors that can cause an infection of the host might mistakenly be used.
- The lentivirus vector could become activated by another virus infecting the cell and become infectious.
- They can create molecules that can be toxic to the cell.
- Infected patients could pass on a new and infectious virus to people around them.

Researchers need to consider these risks when developing clinical trials using lentivirus vectors. They need to ensure that they are not using vectors that can cause an infection in the host. They also need to ensure that the vector that they are using has a low risk of causing unintended mutations.

Exome sequencing

Definition

Exome sequencing (ES) is a technique developed since 2007 for identifying or determining the exact order of all the portions of the genes in an organism's genome that code for proteins. These gene portions are called exons, and the total of all the exons in a genome is called the exome. The human exome accounts for 180,000 exons, or 1%–2% of all the DNA in an individual human's genome—about 30 million base pairs. The word *exon* was formed from "EXpress" and "regiON," because the exon is the region of the gene expressed in the protein produced by the gene. Exome sequencing is also called whole-exome sequencing, abbreviated WES.

In most DNA sequences, the exons are separated by noncoding portions of the gene called introns. The word *intron* is derived from "INTragenic" and "regiON," because the introns are located inside the gene (intra-genic) between the exons. Prior to the process of amino acid transcription, the introns are spliced out of

messenger RNA, leaving only the exons to transcribe the final gene product.

Description

ES (or WES, for whole-exome sequencing) is a relatively new technique for identifying the protein-coding portions of an individual's genome. It is one of several innovations in DNA sequencing that were developed shortly after 2005, when so-called next-generation sequencing—variously called high-throughput sequencing, massively parallel sequencing, and shotgun sequencing—technology was introduced. Next-generation sequencing was the first major breakthrough in sequencing DNA since the development of the Sanger method in 1977 by Frederick Sanger in the United Kingdom. The Sanger method was time-consuming, expensive, and limited to sections of DNA that were only about 1,000 base pairs (bp) in length. As a result, using the Sanger sequencing method—which was state of the art in 1990—means that the Human Genome Project required 13 years to complete its sequencing of a human genome, and the task had to be divided among several different research centers.

Next-generation sequencing is both faster and less expensive than the original Sanger method, as it can sequence many strands of DNA at the same time and also sequence longer sections of DNA than the Sanger method allowed. The phrase "shotgun sequencing" refers to the fact that next-generation sequencing methods break up, or shear, an organism's entire genome into many small fragments, similar to the effect of a shotgun blast. The fragments are sequenced individually, then read by a computer that identifies overlapping segments in the fragments and uses these overlaps to place them in the correct order to reconstruct the full genome.

Exome sequencing begins with shotgun shearing of a genome, followed by one of several so-called target-enrichment strategies to identify the exons in the genome and separate them from the noncoding regions. This step is called targeted capture. Several different biotech companies offer kits containing the reagents needed to capture the exons as well as the equipment to interpret the results. After the exons have been captured, the exome is sequenced. It can then be analyzed to identify disease-causing mutations that underlie rare Mendelian diseases.

Purpose

Exome sequencing has been used since 2008 to identify genetic variants that cause rare single-gene diseases. In 2009 the method proved successful in identifying a mutation in a known gene, the *MYH3* gene, as the cause of Freeman-Sheldon syndrome (FSS). In 2010, exome sequencing was used to identify a previously unknown gene on the long arm of chromosome 16, *DHODH*, as

KEY TERMS

Allele—One of several alternative versions of a gene or genetic locus.

Base pair (bp)—Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

Bioinformatics—An interdisciplinary scientific field that combines statistics, engineering, mathematics, and computer science to capture and understand biological data.

De novo mutation—A genetic variant that occurs in a child but is not present in either parent.

Exome—The part of a genome formed by all its exons.

Exon—The DNA sequence of a gene that codes for a protein.

Genome—The complete genetic material of an organism.

Genome-wide association study (GWAS)—A method for identifying genes involved in human disease by searching a number of human genomes for small variations that occur more commonly in people with a given disease than in those who do not have the disease.

Genomics—A subspecialty of genetics that focuses on the study of the genome.

Intron—Any of the portions of a gene that does not code for amino acids.

Mendelian disease—Any genetic disease that is caused by a single gene and follows the basic Mendelian patterns of inheritance.

Next-generation sequencing—A general term for massively parallel sequencing of large portions of DNA base pairs, performed by first fragmenting the DNA, reading the individual fragments in parallel, and then reassembling the reads to obtain the sequence of the entire genome.

Nucleotide—A building block of a nucleic acid (DNA or RNA), consisting of a sugar molecule, a phosphate

group, and one of the nitrogen-containing bases (adenine, cytosine, guanine, and thymine in DNA; adenine, cytosine, guanine, and uracil in RNA).

Phenotype—The physical appearance and biochemical characteristics of an organism resulting from the interactions between its genotype (genetic makeup) and the environment.

Proband—In genetics, a particular subject (person or animal) being reported on or studied. In most cases, the proband is the first affected member of a family with a genetic disorder who brings the condition to the attention of doctors and researchers.

Sanger sequencing—The earliest method for sequencing DNA, devised by Frederick Sanger in the United Kingdom in 1977 and used as the primary method of sequencing until 2002. It is still used to validate the results of so-called next-generation sequencing. The Sanger method involves first separating the two strands of DNA and then adding chemically altered forms of the adenine, cytosine, guanine, and thymine bases. The altered bases stop the process of DNA replication as they are added to the strand of DNA, resulting in a series of short pieces of DNA. These short pieces are placed in order from shortest to longest in order to read the entire original sequence of DNA.

Structural variations—Variations in the structure of an organism's chromosome that are larger than single-nucleotide polymorphisms but smaller than a chromosome abnormality. Structural variations can include deletions, duplications, and insertions as well as copy number variations. Many structural variations are linked to genetic diseases but many more are not.

Throughput—In general, the rate at which data can be processed, or the work that a computer can do in a specific period of time. High-throughput sequencing refers to any of a set of technologies that can produce large numbers of DNA sequences concurrently.

the cause of Miller syndrome, an extremely rare genetic disorder characterized by multiple facial malformations. In addition to identifying genes associated with known single-gene disorders, exome sequencing has also been found helpful in identifying *de novo* mutations, particularly in multiple malformation syndromes and mental retardation.

Exome sequencing has several advantages over older methods of identifying disease-causing alleles for rare disorders. Genome-wide association studies (GWAS), which are used to identify genetic variations across a large number of different human genomes, are useful in identifying genetic markers of common diseases like asthma, type 2 diabetes, or heart disease, but are not

QUESTIONS TO ASK YOUR DOCTOR

- Given my personal and family history, would you recommend exome sequencing for me?
- What is your opinion of direct-to-consumer exome sequencing?
- Do you think exome sequencing will continue to be used in research and clinical practice, or do you think it will become obsolete as whole-genome sequencing continues to drop in price?

useful in identifying the mutations that cause rare disorders. The scanning of a large number of different genomes that is used in GWAS is not helpful in studying rare disorders because these disorders have few affected families with probands who can be studied. In addition, many of these rare disorders affect the ability of probands (the initial individuals identified as having the disorder) to reproduce, which increases the difficulty of studying inheritance patterns in these disorders.

Second, whole-exome sequencing is an efficient method for looking for disease-causing mutations because it targets the protein-coding region of the genome. The exome is thought to account for 85% of disease-causing mutations, as most genetic disorders result from defective proteins. By contrast, the noncoding portions of genes have relatively minor effects on human phenotypes (the externally observable characteristics of an individual that result from the interactions between the organism's genetic makeup and its environment). The exome thus represents the portion of the genome that contains genetic variants with large effects on health. Exome sequencing of a small number of individuals affected by a rare genetic disorder but unrelated to one another thus facilitates the identification of the gene that causes the disorder.

A third consideration that favors exome sequencing is its lower cost. While next-generation sequencing makes it possible to sequence an entire individual human genome (called whole-genome sequencing or WGS) in a reasonable amount of time (days to weeks, as compared to the 13 years that the Human Genome Project required to sequence the first complete human genome), WGS is about five or six times as expensive as whole-exome sequencing or WES. Although the cost of WGS continues to decline as the power of computers increases, sequencing a complete human genome cost about \$6,000 as of April 2015, according to the National Human Genome Research Institute. According to the Broad Institute in Cambridge, Massachusetts, whole-exome sequencing

can be performed for about \$1,000. The lower cost of WES as well as its focus on the protein-coding regions of the genome makes it a practical approach to identifying disease-causing mutations associated with monogenic disorders.

Limitations

Whole-exome sequencing has several limitations as well as advantages. First, the phrase “whole-exome” is a bit of a misnomer because even the most accurate targeted capture methods as of 2015 missed between 3% and 5% of the exons in an exome. If a suspected disease-causing mutation is thought to be in the missing section of the exome, it must be identified by another method, most often polymerase chain reaction, although whole-genome sequencing can also be used. Second, not all protein-coding sections of the human genome have yet been identified, thus current exome sequencing can target only known exons. Third, exome sequencing will not detect harmful mutations in noncoding sections of the genome that are known to be associated with certain genetic disorders. These noncoding sections include structural variations in chromosomes and microRNA molecules.

Fourth, whole-exome sequencing identifies a large number of single-nucleotide variations (SNVs) of unknown significance as well as potentially disease-causing mutations. The number of such variations ranges from about 24,000 in African American samples to 20,000 in Caucasian Americans. Although there are several strategies for filtering out the nonproblematic variations, there are usually several hundred SNVs remaining that require sorting and analysis by genetics professionals. A related problem is the discovery of what are called off-target mutations (sometimes called secondary or incidental findings) during whole-exome sequencing. An off-target mutation is one that is not relevant to the condition for which the test was ordered but indicates the likelihood of future disease in the person being tested. An example would be the discovery of a mutation in one of the genes linked to breast cancer—an adult-onset disorder—in a small child being tested for mutations related to vision disorders.

The present limitations of WES have led to a debate in the field of genomics as of 2015 regarding the future utility of exome sequencing. Some researchers predicted that WES would have a limited “shelf life” and would be replaced entirely by WGS as the cost of whole-genome sequencing continues to drop. Others maintained that the shorter time frame required to perform WES (1/15 the time required to sequence an entire human genome) and the smaller amount of data requiring storage

(1/15 the volume required for WGS) would guarantee an ongoing place for whole-exome sequencing.

Applications

As of 2015, WES was used in both genetic research and clinical diagnosis.

Research

Since the earliest discoveries of disease-causing mutations in 2009, exome sequencing has been used in research to study subjects other than disease-causing mutations in humans. These other fields include the need to identify disease-causing mutations in non-human primates, including rhesus monkeys and chimpanzees; to obtain new insights into the process of human evolution; and to study population genetics (the study of changes in allele frequency and distribution within a specific population). The interpretation of these findings requires collaboration from specialists in many disciplines, including experts in the field of bioinformatics as well as geneticists, biologists, anthropologists, and epidemiologists.

Clinical medicine

Exome sequencing has been used for clinical diagnostic purposes since 2009. In 2009 a group of clinicians at Yale discovered that a 10-year-old boy initially thought to have Bartter syndrome, a rare kidney disorder characterized by low levels of potassium in the blood, actually had congenital chloride diarrhea (CCD), a condition caused by a previously unknown mutation in the *SLC26A3* gene. Since 2009, new causative genes for at least 150 inheritable disorders have been identified using either whole-exome or whole-genome sequencing.

The rapid pace of these new discoveries has led to a set of new ethical as well as practical concerns for high-quality patient care as well as the most effective use of advanced technologies. In 2012 the American College of Medical Genetics and Genomics (ACMG) drew up a policy statement regarding the clinical applications of whole-exome and whole-genome sequencing. Their first recommendation concerned the indications for WES and WGS in clinical diagnostic assessment. The ACMG recommended WES or WGS in the following situations:

- The patient's phenotype or family history suggests a genetic cause, but the patient's phenotype does not resemble that of a genetic disorder for which a clinical single-gene test currently exists.
- The patient has a genetic disorder with a high degree of genetic heterogeneity, making WES or WGS a more practical approach because both methods can analyze a number of different genes simultaneously.

- The patient is likely to have a genetic disorder, but the tests presently available for that disorder have failed to obtain a diagnosis.

The ACMG also recommended pretest genetic counseling regarding the expected outcomes; the likelihood of and reporting of off-target or secondary findings; and discussion of which results will or will not be disclosed to the patient. In addition, the ACMG recommended obtaining informed consent from the patient for the use of findings of unknown significance that might be a subject for future research. Ongoing questions related to both WES and WGS include issues of permanent versus temporary data storage; patient confidentiality; obtaining informed consent from children and adolescent patients; and disclosure to insurance companies.

Direct-to-consumer exome sequencing

Various companies based in the United States and China began offering direct-to-consumer (DTC) exome sequencing tests as early as 2011. Although private individuals have been able to purchase WGS for several years from such companies as Illumina, the whole-genome tests cost several thousand dollars and were marketed primarily to researchers. In 2011, a company called 23andMe offered a whole-exome sequencing test for \$999 but was forced to drop the health-related results formerly sent to customers when the Food and Drug Administration ordered the company to discontinue its personal genome service. Another company, Gene by Gene, which is based in Houston, offers WES for about \$895, while Beijing Genomic Institute (BGI) in China offers WES for about \$500.

Genetics professionals are concerned about the trend toward DTC exome sequencing, as it has already led to anxious consumers consulting genetic counselors on their own. As whole-exome sequencing yields large amounts of complex data that are time-consuming to interpret, DTC marketing of WES is presently more likely to confuse and worry consumers than to help them.

Expanded carrier screening (ECS)

Definition

Expanded carrier screening (ECS) refers to tests designed to determine whether someone is a carrier for one or more genetic conditions and at risk for having a child with a genetic condition or disorder. ECS tests for many genetic conditions at the same time. It is typically used to screen couples without a personal or family history of a genetic condition. It can be done before or during pregnancy.

Description

The goal of carrier screening is to identify people at increased risk for having a child with a genetic condition or disorder. About 2% to 4% of couples are at risk for having a child with a condition or disorder that can be detected through ECS. If the parents are found to be carriers, then testing needs to be done on the fetus to see whether the fetus has inherited the condition.

Historically, carrier screening was only offered to parents who were thought to be at a higher risk for having

a child with a genetic condition; that is, parents with a personal or family history of a genetic disease or those with an ancestry that put them at higher risk. For example, people of Mediterranean background might be offered β -thalassemia carrier screening, and those with Ashkenazic Jewish heritage might be offered Tay-Sachs screening. Carrier screening also tested only at-risk parents for one or a few genetic conditions, which is called targeted carrier testing.

Targeted carrier testing misses many couples who are carriers since most do not have a family or personal history of a genetic condition. Also, most do not fall into an at-risk category based on ancestry, or it is difficult to determine their ancestry.

Testing the general population for multiple genetic conditions at one time became feasible with the discovery of new technologies and decreased costs. The decrease in costs and desire of healthcare providers to offer more equitable carrier screening to the general population prompted the development of the first ECS tests in 2009.

ECS is not recommended for families that have a family history of a particular genetic disease. In these cases, targeted carrier testing for the specific disorder is preferable. Targeted carrier testing can test for a greater range of variations for a particular disorder than ECS can.

Types of conditions ECS identifies

Most ECS panels test between 100 and 300 genetic conditions. About 30% to 40% of people who are tested are found to be carriers. Around 1% to 3% of couples who do ECS are found to be at risk for having an affected child. ECS tests typically determine whether someone is a carrier for one or more autosomal recessive and X-linked genetic conditions.

A person who has an autosomal recessive condition has a pathogenic (disease causing) variant (mutation) in both copies of a gene that causes this condition. This gene is found on one of the 22 non-sex chromosomes. The person's parents are each carriers of one variant. A carrier for an autosomal recessive genetic disease has a pathogenic variant in one copy of a gene and one functioning copy of that same gene. Carriers often do not have symptoms because they have one functioning copy of the gene. Two carriers of an autosomal recessive condition have a one in four or 25% chance of passing it on to their children.

An X-linked condition results from a pathogenic variant on a gene on the X chromosome. Females have two X chromosomes, and males have an X and Y chromosome. These are called the sex chromosomes. Females get one X chromosome from their mother and one from their father. Males get one X chromosome from their

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Autosomal recessive—A pattern of inheritance in which both copies of a defective gene on a nonsex chromosome are required for a genetic disorder to manifest in a person.

Carrier—Person who has a pathogenic variant (mutation) in one copy of a gene. Carriers often do not have symptoms. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

Cell—Building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle, and connective tissue.

Chromosome—The package of DNA found in each cell of the human body apart from the red blood cells. Humans have 22 pairs of autosomes (1 to 22) and one pair of sex chromosomes (XY). Females have two X chromosomes, and males have an X and Y chromosome. Normally, individuals inherit one chromosome of each pair from their mother and one from their father.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T),

and cytosine (C). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The sequence of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid.

False negative—A test result that indicates that a disease or condition is not present when it actually is.

False positive—An error in which a test result incorrectly indicates the presence of a disease that is not actually present.

Gene—A sequence of bases in a DNA sequence that contains the instructions for one protein.

Panel—A specific ECS test.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Residual risk—The chance that an individual may still be a carrier for a certain condition even though the person screened negative.

Targeted carrier testing—Testing to see whether a person is a carrier of only one or a few conditions that the person is at risk for based on personal or family history or ancestry.

Variant—Change in the sequence of DNA.

X-linked—A condition caused by a pathogenic variant on the X chromosome.

mother and one Y chromosome from their father. Males are affected when they inherit the gene variant from their mother. In most cases, a female who inherits a pathogenic variant in one copy of the gene that causes the X-linked condition does not have symptoms. She is called a carrier. There are exceptions; some carrier females can have symptoms. Carrier females have a one-in-two or 50% chance that their sons will be affected and one-in-two or 50% chance that their daughters will be carriers. Daughters of affected males will all be carriers, and sons of affected males will not be affected.

Some ECS panels test for autosomal dominant disorders. Someone with an autosomal dominant condition has a pathogenic variant (mutation) in one copy of a particular gene. Individuals with an autosomal dominant condition have a one-in-two (50%) chance of passing it on to their children. ECS testing for autosomal dominant

conditions can unexpectedly diagnose a genetic disease in the parent undergoing testing.

How ECS testing is performed

Either both individuals in a couple are tested at once, or they are tested sequentially. If testing is done during pregnancy, then testing of both parents at once is recommended. This is so that testing of the fetus, if required, can be done earlier. ECS panels that test for autosomal dominant conditions should be done on both parents at the same time because their child may be at risk for inheriting the condition if either parent has a pathogenic variant.

Testing can be done through a blood draw, collection of saliva, or by scraping cells from the cheek. If both parents are carriers for a variant in the same gene, then the child can be tested to see whether the child has inherited the condition. Testing of the fetus can be done through

QUESTIONS TO ASK YOUR DOCTOR

- Do you offer ECS testing?
- Which ECS test would you recommend?
- What conditions are tested for by the ECS you offer?
- How accurate is the ECS test?
- Does the ECS test you offer test for autosomal dominant conditions?

amniocentesis, in which fetal cells are taken from the amniotic fluid surrounding the fetus or by chorionic villus sampling (CVS) in which a sample of placental tissue is taken.

Although ECS can be performed during pregnancy, it is better to do it before gestation. Early testing increases the parent's options. For example, carrier parents may choose not to have children; to adopt; or to use a donor egg or sperm. They may also choose in vitro fertilization (IVF) with pre-implantation diagnosis, which allows the doctor to implant only embryos without the identified genetic condition.

ECS accuracy

ECS tests vary in accuracy. The accuracy can be lower for nonclinical tests, such as direct-to-consumer genetic tests performed at home. The accuracy of testing for some conditions versus others will vary even within the same ECS test. False positive and false negative rates indicate the accuracy of a test. The false positive is a result that incorrectly states that the person is a carrier. False positives typically happen if a mistake happens during the test. For most ECS tests, false positives for common conditions and variants are rare. If a very rare variant is detected, then it is more likely to be a false positive. A false positive can sometimes happen if a variant is mistakenly attributed to a particular condition.

In the case of false negatives, the individual is incorrectly identified as not a carrier. The false negative rate is higher than the false positive rate for many conditions in many ECS tests. False negatives can happen if the lab makes a mistake and misses the variant. More often, false negatives happen because the ECS panel does not test for the variant in the person being tested. This outcome occurs because the variant is not yet known to cause the disease, or because this particular panel does not test for this variant. The false negative rate depends on the number of variants that are tested for a particular condition. The false negative rate can differ among different labs

that may test for different variants. Even when a person screens negative for a condition, there is a residual risk. Residual risk for a particular condition is the chance that the person is actually a carrier even though the person screened negative. For more common conditions the residual risk may be known, but it is not known for many of the rarer conditions included in an ECS test.

Reasons to use ECS

Couples use ECS for various reasons:

- They may choose not to have children if they are carriers.
- They may choose to adopt or use donor eggs or sperm if they are carriers.
- They may choose to use in-vitro fertilization and only implant normal embryos if they are carriers.
- They may want reassurance that they are not carriers.
- If they learn they are carriers, they may choose to do prenatal testing for reassurance or to help prepare for a child with a genetic condition.
- If they learn they are carriers, they may seek prenatal testing and choose to terminate an affected pregnancy.

Potential issues

There are a number of issues that parents need to consider when deciding whether to use ECS. For example, not all carriers are identified through ECS, and not all conditions can be identified. Also, results may be incorrect.

In addition, some conditions and variants detected through ECS have variable symptoms. Some people with the condition may have no symptoms at all. In such cases, it can be difficult to predict the severity of the condition for an affected fetus.

Some ECS panels test for autosomal dominant conditions. In these cases, parents who undergo testing may unexpectedly be diagnosed with a genetic condition. Some people may not want this information.

Most ECS panels test for conditions that start in childhood and are lethal or moderate to severe. Some test for adult-onset conditions that parents might not want to know about.

There can also be emotional risks to testing. It can be upsetting for individuals to find out they are carriers even if their fetus is not at risk. If one parent is tested at a time, then the wait for the results for the other person can be unsettling. During gestation, parents can be troubled to learn that their child has a genetic condition.

Choosing a test

ECS tests vary greatly. The accuracy between these tests also can vary significantly. Before choosing a test, individuals should find out more about the false positive and false negative rates for different conditions that are included in the ECS panel. It is important to choose a panel from a reputable lab that is recommended by a healthcare provider. Testing for more conditions is not always better because some of the conditions tested for may be rare and not much may be known about them. Individuals may also want to choose an ECS test that includes pre- and post-test genetic counseling, or they may ask their healthcare provider if they can have genetic counseling before deciding if they want to be tested.

Individuals may also want to choose a test based on the type of conditions it seeks to identify. Different ECS panels vary significantly. For example, a 2017 survey of ECS testing found that the number of conditions tested for varied from 40 to 1,792. The types of conditions tested for also vary among tests, and this survey found that only three conditions were tested for by all ECS tests.

Individuals who are concerned about a particular condition should confirm that the condition is included in the panel they use. Furthermore, they could check to see whether the chosen ECS panel tests for irrelevant conditions. Individuals should also determine what information they want to discover. For example, they may not want to know about conditions that can have mild or no symptoms. Similarly, they may not want to find out about conditions with symptoms that first appear in adulthood.

Fabry disease

Definition

Fabry disease is a genetic condition that typically affects males. It is caused by deficiency of an enzyme, a chemical that speeds up another chemical reaction. Fabry disease can affect many parts of the body including the kidneys, eyes, brain, and heart. Pain in the hands and feet and a characteristic rash are classic features of this disease.

Description

The symptoms of Fabry disease were first described by Dr. Johann Fabry and Dr. William Anderson in 1898. The enzyme deficiency that leads to the disease was identified in the 1960s. Fabry disease is caused by a change (mutation) in the *GLA* gene. This gene is responsible for the production of the enzyme alpha-galactosidase A. Alpha-galactosidase A normally breaks down globotriaosylceramide, which is a natural substance in the body that is made of sugar and fat. A mutation in the *GLA* gene leads to a decrease in alpha-galactosidase A activity, which, in turn, leads to an excess of globotriaosylceramide. The excess globotriaosylceramide builds up in blood vessels (veins, arteries, and capillaries) and obstructs normal blood flow. It also builds up in parts of the skin, kidneys, heart, and brain. It is this buildup that inhibits normal function and leads to the symptoms associated with the disease.

The symptoms of Fabry disease are variable. Some individuals with Fabry disease have severe complications, while others have very mild symptoms. The first sign of the disease may be a painful burning sensation in the hands and feet (acroparesthesia). A red rash, most commonly between the belly button and the knees (angiokeratoma), is also common. The outer portion of the eye (cornea) may also become clouded in individuals with Fabry disease. The progressive buildup of

globotriaosylceramide can also lead to kidney problems and heart disease in adulthood.

Genetic profile

The gene that produces alpha-galactosidase A is located on the X chromosome. It is called the *GLA* gene. Since the *GLA* gene is located on the X chromosome, Fabry disease is considered to be X-linked. This means that it generally affects males.

A person's sex is determined by his or her chromosomes. Males have one X chromosome and one Y chromosome. Females, on the other hand, have two X chromosomes. Males who possess a mutation or change in their *GLA* gene will develop Fabry disease. Females who possess a mutation in one of their *GLA* genes typically do not develop many of the symptoms associated with Fabry disease. This is because a female's other X chromosome does not have the mutation, and the normal chromosome can take over the function of the abnormal chromosome and keep her from getting the disease. However, these women are considered to be carriers. If a woman is a carrier, she has a 50% risk with any pregnancy to pass on her X chromosome with the mutation. Therefore, with every male pregnancy she has a 50% risk of having an affected son, and with every female pregnancy she has a 50% risk of having a daughter who is a carrier.

Demographics

Fabry disease affects approximately 1 in 40,000 live births; about 5,000 people in the United States have been diagnosed with the disease as of 2021. It occurs evenly among all ethnic groups. Almost always, only male children are affected. Although female carriers of the disease occasionally develop symptoms of the disease, it is rare for a female carrier to be severely affected.

Signs and symptoms

The signs and symptoms of Fabry disease vary. Some individuals with Fabry disease have many severe

KEY TERMS

Acroparesthesia—Painful burning sensation in hands and feet.

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Angiokeratoma—A skin rash made up of red bumps. The rash most commonly occurs between the navel and the knees.

Blood vessels—A general term for arteries, veins, and capillaries that transport blood throughout the body.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted through either the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Cornea—The transparent structure of the eye over the lens that is continuous with the sclera in forming the outermost protective layer of the eye.

Dialysis—A process in which special equipment purifies the blood of a patient whose kidneys have failed.

Enzyme replacement therapy—Giving an enzyme to a person who needs it for normal body function. The enzyme is given through a needle inserted into the body.

Left ventricular enlargement—Abnormal enlargement of the left lower chamber of the heart.

Mitral valve prolapse—A heart defect in which one of the valves of the heart (which normally controls blood flow) becomes floppy. Mitral valve prolapse may be detected as a heart murmur, but there are usually no symptoms.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Proteinuria—Excess protein in the urine.

symptoms, while other individuals' symptoms may be few and mild. The symptoms typically increase or intensify over time. This progression is caused by the slow buildup of globotriaosylceramide as the person ages.

A painful burning sensation in the hands and feet (acroparesthesia) is one of the first symptoms of Fabry disease. This pain can be severe and may grow worse with exercise, stress, illness, extreme heat, or extreme cold. Another symptom of Fabry disease typically present during childhood is a red rash (angiokeratoma). This rash typically develops between the navel and the knees. Children with Fabry disease may also have a clouding of the outermost portion of the eye (cornea). This symptom is usually diagnosed by an eye doctor (ophthalmologist). The cloudiness may increase with time. A decreased ability to sweat is another common symptom of Fabry disease.

Due to the progressive nature of Fabry disease, most affected individuals develop additional symptoms by age 40. The buildup of globotriaosylceramide in the heart can lead to heart problems. These heart problems can include changes in the size of the heart (left ventricular enlargement), differences in the heartbeat, and leaky heart valves. Mitral valve prolapse is a particular type of leaky heart valve that is common in Fabry disease, even in childhood. The excess globotriaosylceramide can also disrupt normal blood flow in the brain. In some cases this can cause dizziness, seizures, and stroke. The kidneys are other organs affected by Fabry disease. Kidney problems can lead to an abnormal amount of protein in the urine (proteinuria). Severe kidney problems can lead to kidney failure.

Although the symptoms of Fabry disease usually occur in males, female carriers may occasionally exhibit symptoms of the disease. Some carriers experience pain in their hands and feet. Carrier females may also have proteinuria and clouding of their cornea. It is rare for a female to experience all of the symptoms associated with Fabry disease.

Diagnosis

Initially, the diagnosis of Fabry disease is based on the presence of the symptoms. It should also be suspected if there is a family history of the disorder. The diagnosis of Fabry disease is definitively made by measuring the activity of the alpha-galactosidase enzyme. When the activity is very low, it is diagnostic of Fabry disease. This enzyme analysis can be performed through a blood test. Measuring the activity of the enzyme can also detect a female carrier. Women who are carriers of Fabry disease have enzyme activity that is lower than normal.

QUESTIONS TO ASK YOUR DOCTOR

- My physician has recommended that I have a prenatal test for Fabry disease. What will that test show, and why should I have it?
- What are the most common symptoms of Fabry disease?
- My doctor has recommended enzyme replacement therapy for my child with Fabry disease. What does this treatment involve?
- Will enzyme replacement therapy cure my child of Fabry disease? If not, what improvements can we expect to see?

Prenatal diagnosis is possible by measuring the alpha-galactosidase A activity in fetal tissue drawn by amniocentesis or chorionic villus sampling (CVS). Fetuses should be tested if the mother is a carrier. A woman is at risk of being a carrier if she has a son with Fabry disease or if someone in her family has Fabry disease.

Treatment and management

There is currently no cure for Fabry disease. However, enzyme replacement therapy (ERT) is an option. Clinical trials done over a ten-year period and published in 2015 concluded that weekly infusions of ERT (as opposed to the bimonthly infusions that had previously been studied) better slow the decline of renal function. This can increase the lifespan of a patient diagnosed with the disease by up to 13 years. ERT is currently the only FDA-approved treatment for Fabry disease.

Individuals with Fabry disease are recommended to have routine evaluations of their heart and kidneys. Some individuals with kidney disease require a special diet that is low in sodium and protein. Dialysis and kidney transplantation may be necessary for patients with severe kidney disease. Certain medications may reduce the risk of stroke. Finally, individuals with Fabry disease are advised to avoid the situations that cause the pain in their hands and feet to grow worse. In some situations, medication may be required to reduce the pain.

Prognosis

The prognosis for individuals with Fabry disease is good, especially with the arrival of enzyme replacement therapy. Currently, affected individuals survive into adulthood with the symptoms increasing over time.

Facioscapulohumeral muscular dystrophy

Definition

The term *muscular dystrophy* refers to a group of conditions characterized by progressive muscle weakness and atrophy (wasting or deterioration). Many different types of muscular dystrophy have been described, each

of which has unique features and usually a unique underlying genetic cause. Facioscapulohumeral muscular dystrophy (FSHD) takes its name from the parts of the body most affected by the disorder: *facio* refers to the face, *scapulo* to the shoulder blades, and *humeral* to the bone of the upper arm. There were two recognized forms of FSHD as of 2021: type 1 (FSHD1), which accounted for about 95% of diagnosed cases of FSHD, and type 2 (FSHD2), which accounted for the remaining 5%.

Facioscapulohumeral dystrophy is also known as Landouzy-Dejerine muscular dystrophy, after the two French physicians, Louis Landouzy (1845–1917) and Joseph Jules Dejerine (1849–1917), who first described the disorder in 1886.

Description

Facioscapulohumeral (FSH) muscular dystrophy is a disorder that first affects the muscles of the face and shoulders. Usually, the first signs of weakness appear before the age of 20 years. The symptoms of FSH muscular dystrophy vary in severity but are not fatal. One in five people who are affected require a wheelchair after the age of 40 years. The symptoms of FSH muscular dystrophy are quite variable, even within the same family. Some individuals who have the altered DNA sequence involved in type 1 FSHD never develop noticeable symptoms. Most people with the condition first notice weakness in various parts of the upper body in their teenage years. Muscles of the shoulders and face are usually the first to be affected. These may remain the only parts of the body that are affected, or the weakness may progress to include the pelvic muscles, the lower limbs, and the hands. Intelligence and life expectancy are not affected.

Genetic profile

The genetics of FSH muscular dystrophy are complex. As of 2021, two distinct forms of the disorder have been identified, FSHD type 1 (FSHD1), which accounts for about 95% of diagnosed cases of FSHD; and FSHD type 2 (FSHD2), which accounts for the remaining 5%. While FSHD type 1 is inherited in an autosomal dominant pattern, FSHD type 2 has a digenic inheritance pattern, which means that mutations in two different genes are necessary for the affected person to show signs of the disorder.

FSHD type 1

The autosomal dominant inheritance pattern in FSHD type 1 means that an affected person has a 50% chance with each pregnancy to pass the altered gene on to their child. Every person has two copies of every DNA sequence, one inherited maternally and the other inherited

paternally. The altered DNA sequence that causes FSH muscular dystrophy type 1 is the D4Z4 repeat in the subtelomeric region of the long arm of chromosome 4 at 4q35. The term *subtelomeric* means that the region is close to the end of the chromosome. A normal chromosome 4 will contain between 11 and 150 repeats of D4Z4. Within the D4Z4 repeat region is a gene called *DUX4*, which is ordinarily inactive, as the large number of D4Z4 repeats in a normal chromosome contains a high number of methyl groups that keep the *DUX4* gene repressed, or “turned off.”

In an abnormal chromosome 4, however, the D4Z4 region is shortened so that it has only 1–11 repeats. This small number of repeats lowers the number of methyl groups attached to this section of the chromosome, leading to a condition called hypomethylation. Hypomethylation allows the *DUX4* gene to become active (able to code for proteins). Although it is not known as of 2021 exactly how an activated *DUX4* gene causes the muscle weakness characteristic of FSHD type 1, it is thought that the gene codes for an abnormal protein that leads to damage to muscle cells or their premature death.

The *DUX4* gene lies next to a regulatory section of DNA on chromosome 4 that is called a pLAM sequence. A functional pLAM sequence is required for the *DUX4* gene to code for its protein. If this sequence is not functional, the *DUX4* gene cannot produce its protein. Copies of chromosome 4 with a functional pLAM sequence are called permissive, while copies without a functional sequence are called nonpermissive. Because each cell in a person’s body has two copies of chromosome 4, an individual may have two permissive copies of the chromosome, two nonpermissive copies, or one of each. FSHD can develop only in a person with at least one permissive copy of chromosome 4.

When an autosomal dominant condition is present in multiple generations of a family, usually someone from each generation is affected. If a person is the first in his or her family to have an autosomal dominant condition, doctors often assume that the gene mutated for the first time in the egg or sperm that came together to make that person. This type of mutation is called a new, or *de novo*, mutation. About 30% of cases of FSHD type 1 are thought to result from *de novo* mutations in chromosome 4.

FSHD type 2

Although FSHD type 2 is characterized by the same clinical symptoms as FSHD type 1, it is inherited in a different pattern known as digenic inheritance. In digenic inheritance, a person must have mutations in two separate genes in order to develop the symptoms of the disorder. In

FSHD type 2, the person has a normal number of D4Z4 repeats on chromosome 4 at 4q35, but has a mutation in the *SMCHD1* gene on the short arm of chromosome 18 at 18p11.32. This gene codes for a protein that ordinarily adds methyl groups to the D4Z4 region of chromosome 4, which keeps the *DUX4* gene inactive. Mutations in the *SMCHD1* gene reduce the amount of protein available to prevent the activation of the *DUX4* gene. If a person with a mutation in the *SMCHD1* gene has also inherited a permissive copy of chromosome 4, he or she will develop FSHD type 2. In most cases, the patient has inherited the defective copy of the *SMCHD1* gene from one parent and a permissive copy of chromosome 4 from the other parent. Because neither parent has both genetic changes, they will not have any symptoms of the disorder.

Some researchers think that mutations in the *SMCHD1* gene may also increase the severity of FSHD type 1. It is thought that the combination of a shortened D4Z4 region on chromosome 4 and the mutated *SMCHD1* gene increase the level of activation of the *DUX4* gene, resulting in greater muscle weakness and other severe symptoms (including respiratory difficulties) in the patient.

Demographics

FSHD is considered the third most common genetic disorder affecting skeletal muscle. The incidence of FSH muscular dystrophy is approximately 1 in 20,000. Some Dutch references report a higher incidence of 1 in 12,000. Individuals from all ethnic groups are affected.

Signs and symptoms

The severity of the symptoms of FSH muscular dystrophy is highly variable. Some people are debilitated, while others are minimally affected. Symptoms of progressive muscle weakness are usually first noticed in the teenage years, but may be noticed much later. For unknown reasons, more males than females with FSH muscular dystrophy develop symptoms by the age of 30 years. Specific muscle groups are affected. FSH muscular dystrophy does not lead to reduced sensation, nor does it affect intelligence.

Progressive muscle weakness of the shoulders/upper arms and face muscles are usually noticed first. The facial muscle weakness may be noticed as difficulty puckering the lips, smiling, sucking a straw, and closing the eyes while sleeping. The patient may have difficulty pronouncing the letters B, M, and P, which require moving or pursing the lips. Weakness may be asymmetrical; that is, one shoulder may be weaker than the other shoulder. The patient's shoulder blades may protrude, a condition

called scapular winging. The weakness of the shoulder muscles may make it difficult for the patient to lift the arms above shoulder level or throw a ball.

As the condition progresses, the muscles of the lower legs, abdomen, and hips may also become weak. The muscle weakness leads to such abnormal positioning as forward-sloping shoulders and exaggerated curvature of the spine. The patient may also develop a protruding abdomen as a result of weakened abdominal muscles. Although the weakness progresses continuously, the affected individual may perceive it as progressing rapidly at times and slowly at other times. This is because he or she notices the weakness when it results in loss of function. Reflexes are often weaker than normal. Twenty percent of affected individuals eventually require wheelchairs. Foot drop, a gait abnormality, is a common problem in patients with FSHD and increases the risk of dangerous falls.

Describing the weakness as shoulder weakness or facial weakness is an oversimplification. In FSH muscular dystrophy, very specific muscles are affected. Not all of the facial muscles are affected, and not all of the muscles of the shoulder are affected. For example, the biceps and triceps of the upper arm are affected before the deltoids, and the forearm is relatively unaffected.

Many individuals with early-onset FSH muscular dystrophy develop hearing loss of the higher frequencies. Some individuals experience significant hearing loss. Slight changes of the retina are also a symptom of FSH muscular dystrophy. These changes usually do not affect vision, however.

A subset of FSH muscular dystrophy patients are severely affected; as noted above, these individuals most likely have a combination of a shortened D4Z4 region on chromosome 4 and a mutated *SMCHD1* gene on chromosome 18. Individuals with severe infantile FSH muscular dystrophy are symptomatic at birth.

Diagnosis

The diagnosis of FSH muscular dystrophy is based on clinical history (symptoms), family history, and genetic testing. Many evaluations may be necessary to confirm the diagnosis. A thorough physical examination will be performed. Additional testing may include measuring the level of creatine kinase (CK) in the blood; special analysis of tissue obtained by muscle biopsy; and an electromyogram (EMG). Sometimes it is difficult to rule out other possible causes of the muscle weakness.

Molecular genetic testing is available for both types of FSHD. When FSHD type 1 is suspected, the test measures the length of the D4Z4 region of chromosome 4.

KEY TERMS

Creatine kinase (CK)—An enzyme that serves as a marker of the breakdown of muscle tissue. CK levels in blood can be tested to evaluate patients for muscular dystrophy and other disorders of muscle tissue.

De novo mutation—A mutation that arises in a child that is not present in either parent.

Digenic inheritance—A pattern of inheritance in which mutations in two (and only two) different genes are required for the manifestation of a genetic disorder. FSHD type 2 is an example of a genetic disorder with digenic inheritance.

Foot drop—A gait abnormality in which the affected person cannot raise the toes and front of the foot, or raise the foot at the ankle. Foot drop is an indication of a disease of the muscles or nerves; it is not a disease in itself.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Genome—All the DNA within one cell.

Methyl groups—Groups of one carbon and three hydrogen atoms attached to DNA. The number of methyl groups attached to a section of a chromosome influences the level of gene activity (repression or activation).

Methylation—The process in which methyl groups are added to DNA. Methylation typically acts to suppress a gene's ability to code for proteins.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Scapular winging—Abnormal protrusion of the shoulder blades as a result of weak shoulder muscles.

Subtelomere—The section of a chromosome immediately next to the telomere at the end of the chromosome.

Telomere—A specialized region at the end of a chromosome that prevents degradation of genetic material and also prevents the end of the chromosome from fusing with another chromosome.

When FSHD type 2 is suspected, genetic testing combines a screening test for hypomethylation in the D4Z4 region of chromosome 4 with a sequence analysis of the *SMCHD1* gene.

Genetic testing can be performed on fetal cells that are obtained by amniocentesis, performed after the 16th week of pregnancy, or chorionic villus sampling (CVS). CVS is usually performed between 10 and 12 weeks of pregnancy.

Because of the variable severity of FSHD symptoms as well as the different patterns of inheritance, assumptions should not be made about a patient's family history. A thorough clinical examination by an experienced physician may show that a person believed to be unaffected by the disorder actually has mild symptoms of it.

Treatment and management

There is no effective treatment, prevention, or cure for either type of FSH muscular dystrophy approved by the Food and Drug Administration as of 2021. Available treatments help affected persons with the effects of the disease but do not treat the disease itself. Supportive therapies include such orthotic devices as splints and braces, motorized wheelchairs or carts, and sometimes surgery. One surgical procedure that is recommended for some FSHD patients is to attach (fixate) the shoulder blades to the chest wall in order to stabilize the patient's shoulders and improve the range of motion in the patient's upper arms.

Physical and occupational therapy may be helpful to ease discomfort, adjust to physical changes, and lower the patient's risk of falling due to weakness of the ankles and calf muscles. Speech therapy may be necessary to help patients whose ability to articulate certain sounds has been affected by the weakness of facial muscles. Cognitive behavioral therapy (CBT) combined with regular exercise has been found to help relieve the chronic fatigue experienced by many patients with FSHD.

Researchers also continue to study various medications. Previous studies indicated that prednisone may improve muscle strength. However, this finding was not confirmed in more recent studies. Another medication, albuterol, was shown to be beneficial in early studies but the results of the completed study have not been posted.

Prognosis

The prognosis for both types of FSH muscular dystrophy is extremely variable. Prognosis cannot be predicted based on family history. Most people remain

ambulatory, but some do not. Progression is usually slow. One-third of affected individuals over 40 years of age have mild symptoms. A few people with FSH muscular dystrophy never develop muscle weakness. The typical course is weakness that becomes noticeable before the age of 20 years and progresses slowly but continuously throughout life.

Factor V Leiden thrombophilia

Definition

Factor V Leiden thrombophilia is a common genetic disorder that leads to a predisposition or increased chance of developing blood clots in the veins (venous thrombosis).

Description

Factor V Leiden thrombophilia is a disorder caused by an inherited change or mutation in the genetic instructions for making a substance called factor V. The factor V change leads to an increased chance of developing blood clots in blood vessels.

Blood clots form in two steps. In the first step, the body produces platelets that are "sticky" and can form initial plugs or clots when needed. However, the first platelets only form the first temporary plugs. To form a more lasting plug or clot, the platelets release chemicals to attract more platelets and other substances called clotting factors (or clotting proteins). In the second step, the platelets come together with the clotting proteins and form fibers. The fibers weave together and make the clot stronger and longer-lasting.

Individuals who are affected by factor V Leiden thrombophilia have a genetic mutation that makes a longer-lasting, "stickier" form of the clotting factor, or protein, called factor V. This different form of factor V is called factor V Leiden. The factor V Leiden clotting protein lasts longer in the blood because a chemical produced by the body called activated protein C (or APC), which is supposed to help break down the factor V clotting protein, cannot break down the factor V Leiden clotting protein as easily and quickly as it breaks down normal factor V. The factor V Leiden clotting protein breaks down ten times more slowly than an average clotting factor V and accordingly stays in the blood longer.

Since there is longer-lasting, extra-sticky factor V Leiden in the blood, individuals who are affected by factor V Leiden thrombophilia have an increased chance of having free-floating blood clots (thromboses) that can get stuck in the veins and other blood vessels. An alternative name used to describe this condition is hereditary resistance to activated protein C.

Genetic profile

Factor V Leiden thrombophilia occurs when a specific gene on the long arm of chromosome 1 is changed or mutated. This gene is called *F5*. Every person has approximately 30,000 genes that tell their bodies how to form and function. Each gene is present in pairs, since one is inherited from the mother, and one is inherited

from the father. Depending on the inheritance of the changed or mutated *F5* gene, factor V Leiden thrombophilia runs in families in a more severe and less severe form.

The less severe form of factor V Leiden thrombophilia is heterozygous and occurs when an individual inherits only one copy of the altered or mutated gene that causes factor V Leiden. The more severe form of factor V is homozygous and is caused by the inheritance of two non-working or mutated copies of the gene that causes factor V Leiden thrombophilia.

Heterozygous factor V Leiden is inherited in an autosomal dominant pattern. In an autosomal dominant condition, only one changed or mutated copy of the gene for a particular condition is necessary for a person to experience symptoms of the condition. If a parent has an autosomal dominant condition, there is a 50% chance of each child having the same or a similar condition. In heterozygous factor V Leiden thrombophilia, the chance of being affected by venous blood clots is four to eight times greater than for the general population.

Homozygous factor V Leiden thrombophilia is inherited in an autosomal recessive pattern. Such conditions are caused by the inheritance of two changed or mutated copies of a gene. Individuals who are affected by heterozygous factor V Leiden thrombophilia have only one copy of the altered gene. However, when two people with heterozygous factor V Leiden thrombophilia have children together, there is a 25% chance with each pregnancy for their child to inherit two copies, one from each parent. That child then would have two altered copies of the gene and therefore homozygous factor V Leiden thrombophilia. When an individual inherits two non-working copies of the gene that lead to homozygous factor V Leiden thrombophilia, his or her risk of being affected by blood clots stuck in the veins (venous thrombosis) is 80 times higher. Most individuals who are affected by homozygous factor V Leiden thrombophilia develop blood clots at a younger age than those affected by heterozygous factor V Leiden thrombophilia.

Demographics

Factor V Leiden thrombophilia is the most common inherited form of increased blood clotting in the general population. It is more common in the Caucasian population. In the general American and European populations, heterozygous factor V Leiden thrombophilia occurs in approximately 3 to 8 individuals per 100. In the same general American and European populations, homozygous factor V Leiden thrombophilia affects approximately 1 in 5,000 individuals. The frequency in African Americans, Asian Americans, Hispanic Americans, and

Native Americans is smaller than that in Caucasian Americans but is still present at approximately 0.45%–2% of individuals tested. Factor V Leiden thrombophilia is very rare in individuals who have only Asian, African, and indigenous Australian descent.

Signs and symptoms

The symptoms of factor V Leiden thrombophilia vary. Some affected individuals have no physical problems. Others will have complications including blood clots blocking blood vessels (thromboembolism), deep vein thrombosis, unexplained multiple miscarriages and stillborn infants, gallbladder dysfunction, strokes, and heart attacks. The most common physical sign of factor V Leiden thrombophilia is thromboembolism (a blockage in the veins caused by a free-floating clot, or embolus). Venous thromboembolism is most common in the deep veins of the legs (deep venous thrombosis, or DVT, of the legs). Non-specific and common factor V Leiden thrombophilia are suspected in individuals who have had multiple blood clots in the veins (venous thrombosis), more than three unexplained miscarriages, or a family history of individuals with multiple blood clots in the blood vessels.

Diagnosis

Diagnosis of factor V Leiden thrombophilia can be done through a blood coagulation screening test or DNA analysis of the gene that codes for factor V.

The blood coagulation screening test uses the breakdown protein APC in a resistance study to see how quickly the factor V is broken down as compared to other blood clotting factors. An individual with factor V Leiden thrombophilia has factor V that is resistant to being broken down, or is much more slowly broken down, by the APC protein. There are two types of APC resistance screening tests for factor V Leiden thrombophilia. The preferred test is the modified second-generation APC resistance study, because an extra step in the testing (dilution by plasma without factor V) makes it almost 100% accurate, even in pregnant women and patients being treated by medications such as heparin and warfarin.

The DNA or molecular analysis examines the *F5* gene to learn whether the gene is altered or mutated.

Prenatal diagnosis is not routinely offered because the disorder is fairly mild and effective treatment is available.

Potential complications

Factors that may increase the risk of developing abnormal blood clots include:

KEY TERMS

Deep vein thrombosis—A blood clot in one of the systemic veins deep in the body.

Heterozygous—Having two different versions of the same gene.

Homozygous—Having two identical copies of a gene.

Thromboembolism—A condition in which a blood vessel is blocked by a free-floating blood clot carried in the bloodstream.

Venous thrombosis—A condition caused by the presence of a clot in a vein.

- Inheriting two copies of the mutated factor V gene
- Prolonged sitting
- Taking estrogen, including oral contraceptives and hormone replacement therapy
- Pregnancy
- Serious surgeries or injuries (particularly leg fractures, abdominal surgery, and cancer)

DVT and PE are potential complications of factor V Leiden. Although factor V Leiden thrombophilia cannot be prevented, the risk of developing DVT or PE can be reduced in the following ways:

- Regular exercise
- Maintaining a healthy weight
- Frequent movement during travel by plane, train, or vehicle (especially if the trip is longer than four hours)
- Breaks at least once every two hours on a long road trip
- Wearing compression stockings

Treatment and management

The treatment and management of individuals affected by factor V Leiden thrombophilia are focused on prevention of floating blood clots (thrombosis) and thromboembolism. The management of affected individuals should be overseen by a hematologist who specializes in blood clotting disorders and a general practitioner or internist who can work closely with the hematologist.

At different times of life, different specialists may need to be added. For example, when a patient is pregnant, a perinatologist or high-risk obstetrician should work with the hematologist. Additionally, individuals who have had a deep vein clot or stroke may need to consult a vascular specialist and/or neurologist.

The physicians managing an affected individual's care should discuss with them the timing, risks, and benefits of taking birth control pills and taking blood thinning anticoagulant medications such as warfarin, aspirin, and heparin. Individuals who are affected by factor V Leiden thrombophilia should also be examined to make sure they do not have other blood clotting disorders in addition to factor V Leiden thrombophilia.

Prognosis

Individuals who are affected by factor V Leiden thrombophilia have a wide range of symptoms and signs. Some will never develop physical signs and symptoms of the disorder, and others will be more severely affected. Most affected individuals will not experience their first clotting event until adulthood. However, those with homozygous factor V Leiden thrombophilia have a significantly increased risk of having symptoms of the disease at a younger age. Treatment and close management of the disorder can reduce the risk of thromboembolism significantly.

Familial adenomatous polyposis

Definition

Familial adenomatous polyposis (FAP) is an inherited condition that typically presents with extensive adenomatous polyps of the colon. These polyps often develop into colorectal cancer in early adult life. Other symptoms are often present as well. These signs include polyps in the upper gastrointestinal tract, malignancies in the brain or thyroid, pigmented retinal lesions, and osteomas.

Description

FAP was first clearly described as a dominantly inherited colorectal cancer susceptibility by Lockhart-Mummery in an article published in 1925. FAP has since served as a paradigm for hereditary cancer and has taught much about the diagnosis, surveillance, and management of colon cancer. It is one of the most clearly defined and well-understood of the inherited colon cancer syndromes. FAP is thought to account for approximately 1% of all cases of colorectal cancer.

FAP is a disorder characterized by the development of hundreds to thousands of glandular colorectal tumors called adenomas or adenomatous polyps, meaning that they are benign growths made of the tissue that lines the inside of the colon. They are described as polyps because they protrude from mucous membranes. In FAP, these tumors generally develop by the second or third decade of life. They are found in the internal lining of the colon and the rectum, with a particular affinity for the left side of the colon or the rectosigmoid. By themselves, these polyps are benign, but they have the ability to become malignant, leading to colorectal cancer. If the polyps are not treated properly, it is almost certain that a person affected with FAP will develop colorectal cancer by the age of 40.

Other clinical findings that may be associated with FAP include polyps in the upper gastrointestinal tract, extraintestinal manifestations such as osteomas and epidermoid cysts, desmoid formation, retinal lesions, and malignant changes in other organs. Symptoms are thought to manifest anywhere between the ages of 16 and 50 years.

FAP is also known as familial polyposis coli (FPC) and adenomatous polyposis coli (APC). Gardner syndrome and Turcot syndrome are variants of FAP. Gardner syndrome is used to describe patients with FAP and the extracolonic symptoms of osteomas, soft tissue tumors, desmoids, and dental abnormalities. Turcot syndrome is

used when FAP is seen in conjunction with tumors of the central nervous system called medulloblastomas (cerebellar tumors that occur in childhood). Attenuated FAP (AFAP) is another variant of FAP. In this condition, individuals present with fewer polyps, usually fewer than 100 in number and often in the right colon. Patients with AFAP may have a later onset of cancer than those with classic FAP.

Genetic profile

FAP is inherited in an autosomal dominant pattern; thus an affected person has a 50% chance of passing the disease on to each of his or her children. It is almost 100% penetrant, meaning that nearly everyone who carries the gene mutation will show signs of the disorder. The majority of patients with FAP inherit the mutation from one of their parents. However, in approximately 25% of cases, there is no family history of the disorder and FAP occurs because of a new mutation in the affected individual.

The majority of cases of FAP are due to mutations of the *APC* gene, located on the long arm (or “q” arm) of chromosome 5. This gene encodes a protein that is important in cell adhesion and signal transduction. More than 300 different *APC* mutations have been described in FAP patients. Most *APC* mutations seen in individuals with FAP result in translation of a protein that is shorter than normal. This shortened protein cannot function properly.

Studies have shown that the type and location of the *APC* mutation seems to correlate to the clinical symptoms that a person manifests. For example, if the mutation is located near the center of the gene, colonic polyps tend to be more dense and numerous. A mutation toward the ends of the gene often leads to polyps that are fewer and more sparse, as in attenuated FAP. Additionally, mutations at one particular end (the 3' end) of the *APC* gene seem to be associated with a higher risk of desmoid formation. However, it is known that family members who carry identical mutations often have different clinical features. This finding suggests that modifying genes and/or environmental factors also influence the expression of the *APC* gene mutation.

The *APC* gene is a tumor-suppressor gene, meaning that its function is to control cell growth. When *APC* is mutated, it does not function correctly and allows cells to grow out of control. This results in tumors that may lead to cancer. Carriers of mutations in *APC* inherit a germline mutation in one allele of the gene. Thus, in every one of their cells, one gene does not make the *APC* protein, but the corresponding gene on the other chromosome continues to produce the functional protein.

Thus, tumor suppression continues. However, if a somatic mutation occurs in the remaining functional gene, no APC protein is made, tumor suppression fails, and tumors develop. These somatic mutations occur in various parts of the body at various times, leading to multiple tumors forming in distinct parts of the body over a period of time. In the case of FAP, many of these tumors are confined to the colon but can occur in other organs as well.

Demographics

Approximately 1 in 7,000 to 1 in 22,000 people are affected with FAP. It is seen in all racial and ethnic groups. Both sexes are affected equally.

Signs and symptoms

Colorectal

FAP is characterized by multiple (more than 100) adenomatous polyps of the colon and rectum. These generally develop after the first decade of life, but the age of onset of adenomas is variable. Fifteen percent of individuals with FAP will show these polyps by age 10, 75% by age 20, and 90% by the age of 30. More than 95% of affected individuals will have adenomatous polyps by the age of 35. Although these polyps are benign, it is inevitable that if left untreated, at least one of the hundreds of polyps will eventually progress to cancer. The majority of cancers appear by the age of 40, and over 90% appear by the age of 45. Symptoms of polyps and/or colorectal cancer may include rectal bleeding, change in bowel habits, iron deficiency anemia, or abdominal pain.

Upper gastrointestinal tract

Many individuals with FAP will develop adenomas in the upper gastrointestinal tract as well. The second portion of the duodenum is particularly prone to these polyps. These adenomas are benign, as they are in the colon, but about 5%–8% of patients with FAP will eventually develop cancer in this area. Duodenal cancer seems to cluster in certain FAP families while being absent in others. Adenomas of other portions of the small bowel may also occur but with lesser frequency.

In people affected with FAP, benign adenomas can also be seen in the stomach. Gastric cystic fundic gland polyps are also common. These are benign polyps that occur in the fundic gland of the stomach, an organ that secretes enzymes and mucus. It is rare for these polyps to become cancerous in individuals of Western origin. However, in Japanese and Korean families with FAP, the risk of gastric cancer is reported to be increased three- to four-fold over the general population.

Ocular, skeletal, and cutaneous

Approximately two-thirds of individuals with FAP will have congenital hypertrophy of the retinal pigment epithelium (CHRPE). These lesions are typically flat, oval, and pigmented. They can be detected by an ophthalmology examination. In FAP patients, these lesions are usually multiple, bilateral, or large. CHRPE does not affect vision, nor does it have the potential to become malignant. However, CHRPE is a very important finding for families with a history of FAP. If CHRPE runs in a family with FAP, all or nearly all affected individuals in the family will have this finding. It can be detected at birth and can thus identify susceptible family members at a young age.

Other manifestations of FAP include dental abnormalities, such as impacted teeth, supernumerary teeth, and congenitally missing teeth. Osteomas can occur, often in the jaw area or on the forehead. Soft tissue tumors, such as lipomas, epidermoid cysts, and fibromas, are observed in some patients with FAP as well.

Other tumors and malignancies

Abdominal desmoid tumors occur in approximately 15% of individuals with FAP. Desmoids are tumors made of connective tissue. Although they are not cancerous, approximately 10% grow very aggressively and can become life-threatening. They may lead to obstruction of blood vessels, the intestine, or ureters. They may also result in abdominal distention and associated pain and discomfort. Over 70% of these tumors develop in women aged 20–40 years, suggesting a hormonal role in their development. Additionally, they occur more commonly in those who have had prior abdominal surgery. Desmoids may occur as part of classical FAP, as part of Gardner syndrome, or sporadically, without the colonic findings of FAP.

Additionally, patients with FAP are at an increased risk for cancers in organs outside of the gastrointestinal tract. These include brain tumors, thyroid tumors, and hepatoblastoma. Hepatoblastoma is a malignant tumor of the liver and occurs in approximately 1.6% of patients with FAP in the first five years of life. Tumors of the adrenal cortex, biliary tract, and pancreas have also been reported.

Diagnosis

FAP can be diagnosed clinically in any individual with greater than 100 polyps in the colon or rectum. The diagnosis is usually made via flexible sigmoidoscopy. This procedure may be done on a routine basis or to investigate possible symptoms of colon polyps and/or colorectal cancer. Flexible sigmoidoscopy involves

inspecting the interior of the rectum and the sigmoid colon or the terminal part of the colon that leads to the rectum. Once polyposis has been established, complete colonoscopy may be necessary to further evaluate the extent of the polyps. Colonoscopy is a more invasive procedure that examines the interior of the entire colon and rectum, rather than only the terminal part.

In regard to a diagnosis in someone who does not yet have colon polyps, retinoscopy, or examination of the retina, can be useful in a family where CHRPE has been associated with FAP. In these families, CHRPE is almost 100% predictive of FAP; thus, if someone shows CHRPE on an ophthalmology exam, it is very likely that he or she is affected with FAP. Although genetic testing yields more certain predictive information, retinoscopy is a relatively inexpensive and noninvasive alternative diagnostic screening measure in families with a history of FAP associated with CHRPE.

Polyps may be first detected by the passage of occult (non-visible) blood in the stool by means of fecal occult blood testing. This testing is also inexpensive and noninvasive and if positive, could indicate that additional testing is needed.

FAP can also be diagnosed by genetic testing. This type of testing may be used to identify someone who is affected but does not yet show any symptoms of FAP. It can also confirm the diagnosis of FAP in someone who has polyposis discovered via flexible sigmoidoscopy. *APC* gene testing is most commonly performed by using a protein truncation test, which looks for the presence of shortened proteins caused by a mutation in the gene. This test identifies approximately 80% of those affected with FAP. The other 20% of patients likely have mutations that do not lead to a shortened protein. It is important to test an affected family member first to determine whether a detectable mutation is present. If a mutation is identified in this affected person, other at-risk family members can be tested for this particular mutation. However, if a mutation is not identified in the affected individual, it is likely that the mutation does not produce a shortened protein. In this case, protein truncation testing would not be informative for the rest of the family.

FAP can also be diagnosed by linkage analysis. This testing identifies approximately 95% of affected individuals; however, blood samples are required from numerous family members, including at least one affected individual. Thus, logistically, this procedure is more complicated than the protein truncation testing.

Treatment and management

There is no treatment for FAP because the genetic abnormality cannot be fixed. Management focuses on

routine surveillance of at-risk and affected individuals for early detection and treatment of colonic polyps and other manifestations.

For individuals diagnosed with FAP, either clinically or via linkage analysis or protein truncation testing, an annual sigmoidoscopy must be performed beginning around the age of ten years. Sigmoidoscopy is preferred because it is less invasive, safer, and will generally detect the polyps in FAP, since they are numerous and located throughout the colon. Colonoscopy may be the screening tool of choice if attenuated FAP is suspected since in this case, the adenomas are fewer in number and may be confined to the proximal region of the colon.

If polyposis is established, complete colonoscopy may be necessary to determine the extent of the polyposis and the timing of surgery. As for surgical intervention, total proctocolectomy (removal of the colon and rectum) is generally favored. In some cases, however, other options may be explored, such as total colectomy (removal of the colon only) with ileorectal anastomosis (the small intestine is attached to the upper portion of the rectum). Another option, a total colectomy with rectal mucosal proctectomy and ileoanal anastomosis, involves removing the entire colon and mucosal lining of the rectum. The ileum then attaches to the anus. Fecal continence is preserved, since the muscular wall and the sensory functions of the rectum are preserved.

All FAP patients require an annual medical examination with palpation of the thyroid and review of systems. Children with FAP should be screened for hepatoblastoma with liver palpation. In some cases, hepatic ultrasonography and determination of serum alpha-fetoprotein levels can be helpful as well. Upper endoscopy (visual examination of the upper gastrointestinal [GI] tract) should be completed every one to four years to evaluate for gastric and duodenal polyps. Duodenal polyps that increase in size or number or show signs of becoming cancerous may require treatment. This treatment may include evaluation by computed tomography or ultrasonography. If necessary, the polyps may be removed by laser or other procedures.

For at-risk relatives of affected individuals, regular screening should begin between the ages of 10 and 12 years. This screening can be accomplished by protein truncation testing. If the test result is a true negative (i.e., negative result in a person whose affected relative had a positive result), further screening is debatable. This test result should theoretically eliminate the risk of FAP but, in very few cases, laboratory errors or other circumstances may lead to an inaccurate test result. Thus, some experts suggest that flexible sigmoidoscopy should be

KEY TERMS

Benign—Referring to a noncancerous tumor that does not spread and is not life-threatening.

Duodenum—Portion of the small intestine nearest the stomach; the first of three parts of the small intestine.

Epidermoid cyst—Benign cystic tumor derived from epithelial cells.

Fibroma—A nonmalignant tumor of connective tissue.

Hypertrophy—Increase in the size of a tissue or organ brought on by the enlargement of its cells rather than cell multiplication.

Lipoma—A benign tumor composed of well-differentiated fat cells.

Malignant—A tumor growth that spreads to another part of the body, usually cancerous.

Osteoma—A benign bone tumor.

Somatic—Relating to the nonreproductive parts of the body.

performed at ages 18, 25, and 35 years in these individuals, with standard screening thereafter.

After colectomy, continued surveillance of patients with FAP is advised. Ileoscopy is recommended every three to five years. This procedure examines the ileum, or lowest third of the small intestine, and serves to rule out polyps, which may become cancerous with time. Surgical removal of desmoid tumors is invasive but often necessary to prevent recurrence. Various nonoperative treatments have been attempted, such as medication and radiation, none of which have yielded consistent results. Additionally, the examination of any remaining rectal tissue by proctoscopy is necessary every six months to assess for signs of rectal cancer.

As with any abdominal surgeries in people affected with FAP, there is a risk of developing desmoid tumors after the colectomy. If desmoids are suspected, computed tomography is the recommended imaging study. MRI may also be used in certain cases.

Surveillance of the upper GI tract, even after total proctocolectomy, is appropriate because of the incidence of tumors in this area previously discussed.

Prognosis

Without colectomy, the prognosis for individuals with FAP is very poor. Patients who have not undergone

colectomy develop colorectal cancer at an average age of 39 years. The majority of untreated people die from colorectal cancer by the age of 42 years. For those who do undergo a colectomy, prognosis is variable, depending on development and progression of other tumors. For example, desmoids can also be detrimental to those affected with FAP, accounting for 11%–31% of all mortality in these individuals.

Familial dysautonomia

Definition

Familial dysautonomia (FD) is a rare inherited disorder in which affected individuals experience multiple malfunctions of the autonomic nervous system (the part of the nervous system that regulates heart muscle, smooth muscle, and glands) as well as the sensory, motor, and central components of the nervous system. The disorder

is progressive with a continual loss of nerve cells of the sensory and autonomic nervous systems.

Description

Familial dysautonomia is an inherited disorder that occurs almost exclusively in people of Eastern European (Ashkenazi) Jewish descent. FD is one of a larger group of at least five hereditary sensory and autonomic neuropathies (HSANs), conditions that stem from abnormalities of the nervous system. FD was first described in 1949 by pediatricians Conrad Riley and Richard Day. They reported five children, all Jewish, who had an unusual set of reactions to mild anxiety, attributed to a disturbance of the autonomic nervous system. FD is also known as HSAN type III or Riley-Day syndrome. Decades of studies have determined the cause to be a genetic abnormality that causes poor development of nerve cells in the fetus, leading to a progressive loss of nerve cells of the autonomic and sensory nervous systems. The depletion of nerve cells in the autonomic system causes problems with unstable heart rate, blood pressure, and body temperature, as well as gastrointestinal dysfunction, poor motor coordination, and emotional instability. Abnormal development of the sensory nervous system results in poor perception of pain, heat, and cold. This causes affected individuals to injure themselves without being aware of it. This deterioration of the nervous system worsens throughout life and causes multiple health problems that lead to the death of 50% of those affected by the time they reach adulthood.

Genetic profile

FD is caused by mutations (genetic errors) in the *IKBKAP* gene that is found on human chromosome 9, specifically located at region 9q31. The disease is inherited as an autosomal recessive trait. This means that both parents have one copy of the mutant gene but do not have the disease. For these parents, there is a 25% chance with each pregnancy that the child will have the disease.

The *IKBKAP* gene has two known mutations, which together account for 100% of the Ashkenazi Jewish (AJ) cases of FD. There is also a third mutation causing FD that is rarely seen in the non-AJ population. This mutation's gene location has not yet been determined.

Demographics

The abnormal gene causing FD is rare in the general population but has a fairly high incidence in the Ashkenazi Jewish population, originating from Eastern Europe. Both males and females are affected. In the at-risk group, 1 in 27 people is thought to be a carrier of the abnormal gene, with a disease frequency of 1 in 3,700 live births.

Rarely, non-Jewish individuals affected with FD have been reported; a Norwegian child was diagnosed with FD in 1977.

Signs and symptoms

Sensory and autonomic nervous systems fail to develop properly in the fetus. Newborn babies with FD have poor or decreased muscle tone and have poor sucking and swallowing reflexes that make feeding difficult. Affected babies are prone to periods of abnormally low body temperature and are unable to produce adequate tears when crying.

Although symptoms vary markedly, by adolescence, affected children have a 90% likelihood of spinal curvature and experience weakness and leg cramping. They have difficulty concentrating and undergo personality changes including negativism, depression, irritability, and insomnia. Forty percent of affected people have regular vomiting crises in response to either emotional or physical stress. A crisis typically involves one to three days of compulsive vomiting, rapid heart rate, high blood pressure, profuse sweating, and red, blotchy skin.

Between crises, affected individuals may experience low blood pressure when rising to a standing position (postural hypotension). They often have unexplained fevers and may have convulsions in response to even mild infections. Uncoordinated swallowing, reflux of stomach contents, and a poor gag reflex result in food or fluids being misdirected into the trachea and lungs. Aspiration pneumonia (lung infections) often follows. Kidney function may deteriorate with age. Affected people have an abnormal response to low oxygen or high carbon dioxide in their blood. They do not experience the expected "air hunger," or urge to breathe, and may faint or have a seizure. Lack of tears, decreased blink frequency, and insensitivity of the eye to pain from foreign objects can cause inflammation and ulcers of the cornea.

A characteristic sign in those affected with familial dysautonomia is a lack of the sense of taste. This is due to the absence of taste buds on the tongue. Other sensory problems include an inability to feel pain or distinguish between hot and cold temperatures; sensory loss increases with age. Deep tendon reflexes in affected individuals are decreased. Poor speech and motor coordination result in abnormal gait, unsteadiness, tongue thrusting, and abnormal rhythmic facial movements. Growth is stunted, with an average adult height of 5 feet (1.5 meters). Puberty is delayed in both sexes. However, fertility and offspring of affected individuals are normal.

Diagnosis

The presentation of FD varies between affected people. However, of the many manifestations of the disease,

KEY TERMS

Aspiration pneumonia—Lung infection due to food or liquids accidentally getting into lungs.

Autonomic nervous system—The part of the nervous system that regulates heart muscle, smooth muscle, and glands.

Autosomal—Related to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Recessive—Genetic trait expressed only when present on both members of a pair of chromosomes, one inherited from each parent.

five signs are key to the diagnosis: flat, smooth tongue due to lack of taste buds; lack of red flare following histamine injection under the skin; decreased or absent deep tendon reflexes; absence of overflow tears with emotional crying; and parents of Ashkenazi Jewish background.

Other frequent signs are decreased response to pain and temperature, decreased corneal reflexes, unstable blood pressure, low blood pressure when standing erect, red blotching of the skin, and increased sweating. Further supportive evidence of the FD diagnosis includes feeding difficulties, repeated aspiration pneumonia, episodes of low body temperature, breath-holding spells, poor muscle tone, delayed motor development, repeated vomiting, spinal curvature, and poor growth. Prenatal diagnosis, screenings for carrier status, and genetic counseling are available.

Treatment and management

The identification of the FD gene as *IKBKAP* was reported in March 2001, and as the function of the gene is better understood, advancements in treatment are expected. Traditionally, treatment is preventive and supportive. Management of vomiting crises is attempted with drugs, replacement of body fluids, prevention of aspiration of stomach contents into lungs, control of blood pressure, and promotion of sleep. Care of the eyes includes

artificial tears, eyewashes, and topical antibiotics to avoid ulcers of the cornea. Early and adequate treatment of even mild infections is important to avoid triggering vomiting crises. Children should be protected from injury and watched for any unusual swellings or skin discolorations as a way of coping with decreased pain and temperature perception.

Physical and occupational therapy, braces, and other orthopedic aids are used for spinal curvature and poor motor coordination. Speech therapy, special feeding techniques, and respiratory care enhance quality of life. It is important to maintain adequate fluid intake and avoid situations such as high elevations, air travel, and diving underwater where oxygen concentration is decreased. Psychological intervention is helpful to alleviate emotional instability and mood swings in children, and depression, anxiety, and phobias in adults.

Prognosis

The disease process of familial dysautonomia cannot be prevented at present but 80% of affected individuals survive beyond childhood and 50% reach age 30. A few individuals with FD have lived into their fifties. With the determination of the exact location of the gene abnormality, prospects for new treatments and possible gene therapy are on the horizon.

Familial idiopathic basal ganglia calcification

Definition

Familial idiopathic basal ganglia calcification (FIBGC) is a rare progressive neurological disorder that is often hereditary. Characterized by deposits of calcium in the basal ganglia and other parts of the brain, FIBGC causes worsening dementia and the loss of routine motor skills, among other symptoms.

Description

Though calcium is important for good health, this mineral can have harmful effects when it appears in parts of the body where it does not belong. In FIBGC, abnormal deposits of calcium build up in a region of the brain called the basal ganglia (mainly in a section called the globus pallidus) as well as in other parts of the brain. The basal ganglia is the technical name given to clusters of nerve cells that help to initiate and control movements of the body—for example, reaching for a cup of coffee or taking a step forward while walking. The presence of these calcium deposits (referred to as calcifications) interferes with the working of the brain, causing a variety of debilitating mental and physical symptoms that worsen over time. Aside from the basal ganglia, the calcium deposits associated with FIBGC often appear in other areas of the brain such as the cerebral cortex.

Two important effects of the disease are dementia and the loss of learned motor skills. People affected by FIBGC may become overly forgetful and easily confused or disoriented. They have trouble performing relatively simple tasks that require basic hand-eye coordination. Most people with the disease experience slurred speech and problems involving involuntary movements or poor coordination. In addition, personality changes and disorders of mood may develop. In one study of 18 people with FIBGC, half of the participants had symptoms of obsessive-compulsive disorder, major depression, or bipolar disorder. People with FIBGC may have psychotic

symptoms, including hallucinations (visual and auditory), a distorted perception of reality, and paranoid delusions.

As the disease progresses, it causes an increasing degree of paralysis. Muscles become stiff, and physical movement is restricted. Aside from these symptoms, people with FIBGC may experience specific movement disorders: slow, twisting movements of the hands and feet (athetosis) and jerky, rapid movements that resemble spasms (chorea). Vision may also be affected. Because the disease can weaken nerves that carry signals from the eyes to the brain, people with FIBGC may experience partial or almost complete vision loss. Ear infections have also been reported.

The underlying cause of FIBGC is unknown. For this reason, it is described as an idiopathic disorder. Less common names for the disease include Fahr disease, cerebrovascular ferrocalsinosis, non-arteriosclerotic cerebral calcifications, and striopallidodentate calcinosis.

Genetic profile

Research indicates that multiple genes are involved in FIBGC. Almost half of all known cases are caused by mutations in the *SLC20A2* gene, while a small number of cases are caused by mutations in the *PDGFRB* gene and in chromosomes 2, 7, 9, and 14.

The *SLC20A2* gene regulates production of a protein called sodium-dependent phosphate transporter 2 (PiT-2). This protein helps regulate phosphate homeostasis or phosphate levels within the body by transporting phosphate across the cell membrane and into the cell. Mutations in the *SLC20A2* that lead to FIBGC cause the gene to produce a PiT-2 protein that cannot carry phosphate into cells. As a result, phosphate levels in the bloodstream rise. When phosphate levels rise in the blood, they rise in the brain. This elevated phosphate combines with calcium and forms the calcium deposits in the brain that cause FIBGC.

FIBGC caused by mutations in the *PDGFRB* gene are a result of a failure to make a protein called PDGFRB protein, which is important in activating pathways that control many necessary cellular functions. The connection between mutations in the *PDGFRB* gene and FIBGC are not as well understood as those with mutations in the *SLC20A2* gene. Altered PDGFRB protein may affect the cells that line blood vessels in the brain, causing them to take in too much calcium, which could lead to the calcifications of FIBGC. It is also suspected that abnormal PDGFRB proteins could alter phosphate transportation, similar to the mutations in the *SCL20A2* gene, and this may lead to increased phosphate levels in the brain and to the development of calcifications in the brain.

The calcifications found in the basal ganglia of individuals with FIBGC may lead to the characteristics of

KEY TERMS

Calcification—A process in which tissue becomes hardened due to calcium deposits.

Cerebral cortex—The outer surface of the cerebrum made up of gray matter and involved in higher thought processes.

Cerebrum—The largest section of the brain, which is responsible for such higher functions as speech, thought, vision, and memory.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Dementia—A condition of deteriorated mental ability characterized by a marked decline of intellect and often by emotional apathy.

Idiopathic—Of unknown origin.

Neurological—Relating to the brain and central nervous system.

Parathyroid glands—A pair of glands adjacent to the thyroid gland that primarily regulate blood calcium levels.

the disease by disrupting the connection between the basal ganglia and other parts of the brain, specifically the frontal lobe. The frontal lobe is responsible for a person's ability to reason, plan, make decisions, and solve problems. These calcifications may also affect parts of the brain that control social behavior, mood, and motivation. While most people with FIBGC have greater calcification in the basal ganglia, not all people with FIBGC have significant calcification.

Demographics

FIBGC, which appears to affect men and women equally, can appear at any stage of life, from infancy to adulthood. Some people diagnosed with the disease have no family history of the condition, while in many cases FIBGC runs in families and affects members of several generations. In people with dominantly inherited FIBGC, symptoms usually appear anywhere between the ages of 30 and 60. The recessive form emerges at a younger age, between infancy and young adulthood.

Signs and symptoms

People with FIBGC have abnormal calcium deposits in the basal ganglia, primarily in the globus pallidus

region, and often in other parts of the brain. Loss of brain cells in these areas also occurs. The results of electrocardiogram (ECG) studies, which monitor heartbeats, are often abnormal in people with FIBGC. Other signs include malfunctioning parathyroid glands and low blood calcium levels.

The disease causes a variety of physical and psychological symptoms. The head of a person with FIBGC is often smaller and rounder than normal. The condition causes worsening dementia and loss of routine motor skills. Muscle stiffness, movement disorders, and paralysis may occur. Speech often becomes slurred. In some cases, FIBGC causes vision problems and ear infections. Symptoms of Parkinson's disease may develop as well.

Diagnosis

In simple terms, FIBGC is diagnosed when calcifications in the basal ganglia are associated with slurred speech, movement disorders, and other specific symptoms. Special imaging procedures such as a CT scan can detect the presence of calcium deposits. Symptoms can be determined by physical and psychological examinations. Friends or family members with relevant observations of the patient's behavior can also be helpful. Blood tests may be recommended to evaluate blood calcium levels and the parathyroid glands. The appearance of Parkinson-like symptoms is not essential to a diagnosis of FIBGC.

In the absence of other factors, calcium deposits in the basal ganglia do not necessarily indicate the presence of FIBGC. Such calcifications may be due to a metabolism disorder, infectious disease, or a genetic disorder other than FIBGC. In fact, sometimes these calcifications may be present without producing any symptoms or harmful effects, especially in people older than 60.

Treatment and management

There is no cure for FIBGC, which worsens over time. The process of calcification cannot be stopped or reversed. Where possible, clinicians focus on alleviating its various mental and physical effects. These may vary to some degree depending on the individual, even among members of the same family. Lithium carbonate, for example, may be recommended to control psychotic symptoms, while antidepressant medications are often used to combat depression. Ear infections associated with FIBGC can be treated with antibiotics and pain medication.

Prognosis

Due to its damaging effects on the brain and nervous system, FIBGC is eventually fatal.

Familial lipoprotein lipase deficiency

Definition

Familial lipoprotein lipase deficiency is a rare genetic disorder that interferes with fat metabolism. The disease is characterized by the accumulation of triglycerides and chylomicrons (fatty droplets) in the blood. Some common symptoms of this disorder include abdominal pain, nausea, vomiting, and small yellow lesions in the skin.

First described in 1932 by two German physicians, Max Bürger and Otto Grütz, familial lipoprotein lipase deficiency is also known by a number of other names including the following:

- Bürger-Grütz syndrome
- endogenous hypertriglyceridemia
- familial fat-induced hypertriglyceridemia
- familial hyperchylomicronemia
- familial LPL deficiency
- hyperlipoproteinemia type I
- hyperlipoproteinemia type Ia
- lipase D deficiency
- LIPD deficiency
- lipoprotein lipase deficiency, familial

Description

Both fatty tissue (also known as adipose tissue) and muscle normally produce the lipoprotein lipase enzyme. When a person has lipoprotein lipase deficiency, however, he or she is unable to make this enzyme or can make only very low quantities of it. As a result, fat accumulates in the blood. This accumulation of fats in the blood may lead to symptoms such as abdominal pain, nausea, and small yellow fat deposits called xanthomas that appear in the skin.

Genetic profile

Located on chromosome 8, the *LPL* gene carries the blueprint for making the enzyme called lipoprotein lipase. This enzyme breaks down two types of lipoproteins, which are proteins with lipid components (lipids are fats, oils, and other compounds that do not dissolve in water).

There are two types of lipoproteins: chylomicrons, which have the job of transporting fats from the intestine to the blood stream, and very-low-density lipoproteins (VLDLs), which are located in the blood and have the job of transporting fats and cholesterol from the liver to other places in the body. The role of lipoprotein lipase is

KEY TERMS

Autosomal recessive—Describes a genetic trait that appears only when two copies of a mutated gene are present.

Chylomicron—A small fatty droplet.

Lipase—An enzyme that catalyzes the breakdown of a lipid.

Lipids—A class of organic compounds defined by their tendency to dissolve in organic liquids, such as alcohol and ether, but not in water.

Lipoprotein—A complex molecule consisting of a lipid molecule joined with one or more protein molecules.

Prevalence—The number of individuals living with a particular illness within a particular population at any given time. Prevalence is often expressed in terms of the number of individuals per 100 or per 1,000 members of the population.

Triglyceride—A type of lipid consisting of a molecule of glycerol and three fatty acid fragments.

to liberate the fat from chylomicrons and VDLs so the fat can go on to either be used as energy or be stored. Lipoprotein lipase accomplishes this task with the help of another enzyme called apolipoprotein C-II.

When an individual has lipoprotein lipase deficiency, the genetic mutation causes little or no lipoprotein lipase to be produced. Without sufficient enzyme, fat-containing molecules do not break down as they should. They build up in the blood, triggering the symptoms associated with this disorder.

Not all *LPL* mutations are the same. Scientists know of more than 220 different mutations in the gene that can lead to familial lipoprotein lipase deficiency. In many cases, the *LPL* mutation causes one amino acid (amino acids are the building blocks of proteins) to be replaced by another. Specifically, the amino acid glutamic acid takes the place of the amino acid glycine at one position in the enzyme. That seemingly small change is enough to cause the reduction in enzyme function that eventually causes the symptoms of the disorder.

Familial lipoprotein lipase deficiency is an autosomal recessive disorder. It occurs when an individual inherits one mutated *LPL* gene from each parent. The parents may not have the condition and may instead only be carriers. Carriers are individuals who do not develop the disorder themselves but may pass the gene for the disorder on to their children. If both parents are carriers, each

of their children has a 50% chance of being a carrier and a 25% chance of acquiring the disorder. If both parents have lipoprotein lipase deficiency, all of their children will also acquire the disorder.

Demographics

The prevalence of this syndrome is estimated to be about one per million worldwide, although the condition is significantly more common in some parts of the province of Quebec in Canada. In Quebec, the disorder is likely traced to a common ancestor or small group of common ancestors who carried the mutated gene, which then passed down through subsequent generations, increasing in frequency over time.

Signs and symptoms

Symptoms of lipoprotein lipase deficiency generally first appear when the individual is in infancy or early childhood. Symptoms may include one or more (typically several) of the following:

Muscle and bone pain; the presence of xanthomas in the skin, typically on the arms, knees, buttocks, and trunk; jaundice (yellowish coloring of the skin and eyes); and repeated bouts of pancreatitis (inflammation of the pancreas), which may cause symptoms as diverse as abdominal pain, nausea, vomiting, chills, fever, and weakness.

Diagnosis

Initial diagnosis of familial lipoprotein lipase deficiency is based on the presence of symptoms of the disorder, with special attention to possible tenderness and inflammation of the pancreas; accumulation of fatty tissue under the skin, especially the eyelids; and swollen liver and spleen. Confirmatory tests involve a blood test to measure serum triglyceride levels and centrifugation, or spinning, of a blood sample in a centrifuge. Any serum triglyceride result greater than 2,000 mg/dL is suggestive of familial lipoprotein lipase deficiency, although such levels are characteristic of other metabolic genetic disorders as well. The appearance of a milky, fatty material during centrifugation is also suggestive of the condition. Finally, genetic tests are available to determine the existence of a mutation in the *LPL* gene responsible for familial lipoprotein lipase deficiency.

Treatment and management

No cure is available for familial lipoprotein lipase deficiency, but many of the symptoms are treatable. Patients are typically placed on an extremely low-fat diet that is limited to 20 grams of fat per day, or 15% of the individual's daily food intake. Most symptoms clear up after the patient goes on this diet. This diet is designed

QUESTIONS TO ASK YOUR DOCTOR

- How long will I have to remain on this low-fat diet?
- What is the likelihood that family members will also develop familial lipoprotein lipase deficiency?
- If I find out that my child has eaten high-fat foods, is there anything we can do after the fact to counter any potential effects?
- How will I know if my child's pancreatitis is severe enough to warrant a trip to the hospital?
- Are treatments or drugs available for use with familial lipoprotein lipase deficiency?
- Are there support groups or other resources for individuals with familial lipoprotein lipase deficiency and their families?

to keep the patient's blood triglyceride concentration to a level below 2,000 mg/dL. Continued monitoring of triglycerides will help ensure that the dietary measures are sufficient to control symptoms.

In addition, doctors may recommend that patients avoid other substances that are related to higher triglyceride levels. These include:

- Alcohol, and oral estrogens, which are hormones typically used in birth-control or hormone-replacement therapies
- Diuretics, which are so-called "water pills" that rid the body of excess water and cause an increase in urine production
- Isotretinoin, an acne treatment
- Sertraline hydrochloride (Zoloft), an antidepressant medication
- Heart medications known as beta blockers (also called beta-adrenergic blocking agents)

Acute pancreatitis may require a hospital stay. While in the hospital, patients receive intravenous fluids until the inflammation eases and the symptoms subside. This may take several days.

Brothers and sisters of a child who is diagnosed with the disorder should be tested for lipoprotein lipase deficiency, preferably in infancy, so that proper preventive measures can be taken as soon as possible. Adult partners who are carriers and are thinking about having children should consider genetic counseling to fully understand the risks for passing the disorder to their offspring and to receive information about prenatal testing for the disorder.

Prognosis

Individuals are born with familial lipoprotein lipase deficiency, and the first symptoms generally appear during infancy or childhood. No cure exists for this disorder, but those who are willing and able to make the necessary dietary adjustments normally survive the disorder well and live into adulthood. All signs and symptoms, including pancreatitis, skin lesions, and liver and spleen abnormalities disappear within a short time after a low-fat diet has been instituted. Although it is rare, some patients develop other conditions, such as diabetes mellitus, due to pancreatitis.

Familial Mediterranean fever

Definition

Familial Mediterranean fever (FMF) is an inherited disorder of the inflammatory response characterized by recurring attacks of fever accompanied by intense pain

in the abdomen, chest, or joints. Attacks usually last 12–72 hours and can occasionally involve a skin rash. Kidney disease is a serious concern if the disorder is not treated.

Description

FMF can be described as a disorder of “inappropriate” inflammation: An event that in a normal situation causes a mild or unnoticeable inflammation might cause a severe inflammatory response in someone with FMF. Certain areas of the body are at risk for FMF-related symptoms. A serosa is a serous (fluid-producing) membrane that can be found inside the abdominal cavity (peritoneum), around the lungs (pleura), around the heart (pericardium), and inside the joints (synovium). The symptoms of FMF are due to inflammation of one or more of the serosal membranes (serositis). Thus, FMF is also sometimes called recurrent polyserositis.

During an attack, large numbers of neutrophils, a type of white blood cell, move into the affected areas, causing painful inflammation and fever. These episodes may be accompanied by a skin rash or joint pain. In a few cases, chronic arthritis is a problem. Amyloidosis is a potentially serious condition in which proteins called amyloids are mistakenly produced and deposited in organs and tissues throughout the body. Left untreated, amyloidosis often leads to kidney failure, which is the major long-term health risk in FMF.

In most cases, the attacks of fever and pain are first noticed in childhood or adolescence. The interval between these episodes may be days or months and is not predictable. However, during these intervals people with FMF typically lead normal lives. It is not entirely clear what brings on an attack, but people with FMF often report mild physical trauma, physical exertion, or emotional stress just prior to the onset of symptoms. Treatment for FMF involves an oral medication called colchicine, which is highly effective for the episodes of fever and pain, as well as for amyloidosis and the kidney disease that can result from it.

FMF is also known by many other names. They include recurrent hereditary polyserositis, benign paroxysmal peritonitis, familial paroxysmal polyserositis, paroxysmal polyserositis, familial recurrent polyserositis, periodic fever, periodic amyloid syndrome, periodic peritonitis syndrome, Riemann periodic disease, Riemann syndrome, Siegal–Cattan–Mamou syndrome, and Wolff periodic disease.

There are two phenotypes of FMF, classified as type 1 FMF and type 2 FMF. Type 1 FMF is classified as having short episodes of inflammation and symptoms but is more recurrent in nature. The severity and signs and

symptoms of type 1 FMF are dependent on the individual. This is the classic type of FMF. Type 2 FMF is classified as having a diagnosis of amyloidosis only. In this type, no other signs or symptoms are present.

Genetic profile

FMF is a genetic condition inherited in an autosomal recessive fashion. Mutations in the *MEFV* gene (short for Mediterranean fever) on chromosome number 16 are the underlying cause of FMF. More than 80 *MEFV* mutations that cause FMF have been identified. Autosomal recessive inheritance implies that a person with FMF has mutations in both copies of the *MEFV* gene. All genes come in pairs, and one copy of each pair is inherited from each parent. If neither parent of a child with FMF has the condition, it means they both carry one mutated copy of the *MEFV* gene, but also one normal copy, which is enough to protect them from disease. If both parents carry the same autosomal recessive gene, there is a one in four chance in each pregnancy that the child will inherit both recessive genes, and thus have the condition.

The *MEFV* gene carries the instructions for production of a protein called pyrin, named for pyrexia, the medical term for fever. Most *MEFV* mutations change one of the protein building blocks (amino acids) used to make pyrin. The most common mutation replaces the amino acid methionine with the amino acid valine at protein position 694. *MEFV* mutations result in lower amounts of pyrin or a malformed pyrin protein that cannot function properly. As a result, pyrin cannot perform its proposed role in controlling inflammation, leading to an inappropriate inflammatory response.

Demographics

FMF is considered a rare disease worldwide. However, it is very common in Sephardic Jewish, Armenian, Arab, and Turkish people, with an estimated prevalence of about 1 in 200 individuals. Genetic testing has also recently identified numerous cases in additional Mediterranean populations including Ashkenazi Jews, Italians, Greeks, Spaniards, and Cypriots. Occasional cases are also increasingly reported in a wide range of other ethnicities, such as Northern Europeans and Japanese.

Signs and symptoms

The recurrent acute attacks of FMF typically begin in childhood or adolescence. Episodes of fever and painful inflammation usually last 12–72 hours. About 90% of people with FMF have their first attack by age 20. The group of symptoms that characterizes FMF includes the following.

KEY TERMS

Acute phase reactants—Blood proteins whose concentrations increase or decrease in reaction to the inflammation process.

Amyloid—A waxy translucent substance composed mostly of protein that forms plaques (abnormal deposits) in the brain.

Amyloidosis—Accumulation of amyloid deposits in various organs and tissues in the body such that normal functioning of an organ is compromised.

Colchicine—A compound that blocks the assembly of microtubules, which are protein fibers necessary for cell division and some kinds of cell movements, including neutrophil migration. Side effects may include diarrhea, abdominal bloating, and gas.

Exon—The region of a gene that contains the code for producing protein.

Leukocyte—A white blood cell. The neutrophils are a type of leukocyte.

Leukocytosis—An increase in the number of leukocytes in the blood.

Neutrophil—The primary type of white blood cell involved in inflammation. Neutrophils are a type of granulocyte, also known as a polymorphonuclear leukocyte.

Pericarditis—Inflammation of the pericardium, the membrane surrounding the heart.

Peritonitis—Inflammation of the peritoneum, the membrane surrounding the abdominal contents.

Pleuritis—Inflammation of the pleura, the membrane surrounding the lungs.

Pyrexia—The medical term denoting fevers.

Serositis—Inflammation of a serosal membrane. Polyserositis refers to the inflammation of two or more serosal membranes.

Synovitis—Inflammation of the synovium, a membrane found inside joints.

Fever

An FMF attack is nearly always accompanied by a fever, but it may not be noticed in every case. Fevers are typically 100°F–104°F (38°C–40°C). Some people experience chills prior to the onset of fever.

Abdominal pain

Nearly all people with FMF experience abdominal pain at one point or another, and for most it is the most

common complaint. The pain can range from mild to severe and can be diffuse or localized. It can mimic appendicitis, and many people with undiagnosed FMF have had appendectomies or exploratory surgery of the abdomen done, only to have the fever and abdominal pain return.

Chest pain

Pleuritis, also called pleurisy, occurs in up to half of the affected individuals in certain ethnic groups. The pain is usually on one side of the chest. Pericarditis would also be felt as chest pain.

Joint pain

About 50% of people with FMF experience joint pain during attacks. The pain is usually confined to one joint at a time and often involves the hip, knee, or ankle. For some people, however, the recurrent joint pain becomes chronic arthritis.

Myalgia

Up to 20% of individuals report muscle pain. These episodes typically last less than two days and tend to occur in the evening or after physical exertion. Rare cases of muscle pain and fever lasting up to one month have been reported.

Skin rash

A rash described as erysipelas-like erythema accompanies attacks in a minority of people and most often occurs on the front of the lower leg or top of the foot. The rash appears as a red, warm, swollen area about 4–6 in. (10–15 cm) in diameter.

Amyloidosis

FMF is associated with high levels in the blood of a protein called serum amyloid A (SAA). Over time, excess SAA tends to be deposited in tissues and organs throughout the body. The presence and deposition of excess SAA is known as amyloidosis. Amyloidosis may affect the gastrointestinal tract, liver, spleen, heart, and testes, but effects on the kidneys are of greatest concern. The frequency of amyloidosis varies among the different ethnic groups, and its overall incidence is difficult to determine because of the use of colchicine to avert the problem. Left untreated, however, those individuals who do develop amyloidosis of the kidneys may require a renal transplant or may even die of renal failure. The frequency and severity of a person's attacks of fever and serositis seem to have no relation to whether he or she will develop amyloidosis. In fact, a few people with FMF have been

described who have had amyloidosis but apparently no other FMF-related symptoms.

Other symptoms

A small percentage of boys with FMF develop painful inflammation around the testes. Headaches are a common occurrence during attacks, and certain types of vasculitis (inflammation of the blood vessels) seem to be more common in FMF.

Diagnosis

Individually, the symptoms that define FMF are common. Fevers occur for many reasons, and nonspecific pains in the abdomen, chest, and joints are also frequent ailments. Several infections can result in symptoms similar to FMF (Mollaret's meningitis, for instance), and many people with FMF undergo exploratory abdominal surgery and ineffective treatments before they are finally diagnosed. Membership in a less commonly affected ethnic group may delay or hinder the correct diagnosis.

In general, symptoms involving one or more of the following broad groups should lead to suspicion of FMF: unexplained recurrent fevers, polyserositis, skin rash, and/or joint pain; abnormal blood studies; and renal or other disease associated with amyloidosis. A family history of FMF or its symptoms would obviously be an important clue, but the recessive nature of FMF means there usually is no family history. The diagnosis may be confirmed when a person with unexplained fever and pain responds to treatment with colchicine since colchicine is not known to have a beneficial effect on any other condition similar to FMF. Abnormal results on a blood test typically include leukocytosis (elevated number of neutrophils in the blood), an increased erythrocyte sedimentation rate (rate at which red blood cells form a sediment in a blood sample), and increased levels of proteins associated with inflammation (called acute phase reactants) such as SAA.

As of 2021, *MEFV* was the only gene currently known to be associated with FMF. In the United States, several laboratories offer testing for the common mutation p.Glu148Gln in exon 2; mutation p.Pro369Ser in exon 3; and the eight common mutations in exon 10 observed in Mediterranean populations. Because most of the known *MEFV* mutations occur in exon 10, laboratories offering sequence analysis of select exons include exon 10 and variably include other exons.

Similar syndromes of periodic fever and inflammation include familial Hibernian fever and hyperimmunoglobulinemia D syndrome, but both are rarer than FMF.

QUESTIONS TO ASK YOUR DOCTOR

- Occasionally I have a mild fever accompanied by rather severe pain in my joints. How can I find out whether this condition is familial Mediterranean fever?
- What causes this condition?
- What can I do to avoid having episodes of familial Mediterranean fever?
- Should I expect this condition to improve or get worse over time?

Treatment and management

Colchicine is a chemical compound that can be used as a medication, and it is frequently prescribed for gout. Some years ago, colchicine was discovered to also be effective in reducing the frequency and severity of attacks in FMF. Treatment for FMF at this point consists of taking colchicine daily. Studies have shown that about 75% of FMF patients achieve complete remission of their symptoms, and about 95% show marked improvement when taking colchicine. Lower effectiveness has been reported, but there is some question about the number of FMF patients who choose not to take their colchicine between attacks when they are feeling well and thus lose some of the ability to prevent attacks. Compliance with taking colchicine every day may be hampered by its side effects, which include diarrhea, nausea, abdominal bloating, and gas. There is a theoretical risk that colchicine use could damage chromosomes in sperms and eggs or in an embryo during pregnancy, or that it might reduce fertility. However, studies looking at reproduction in men and women who have used colchicine have so far not shown any increased risks. Colchicine is also effective in preventing, delaying, or reversing renal disease associated with amyloidosis.

Studies have shown that an estimated 5%–10% of patients with FMF do not respond to colchicine treatment. Case studies have been published that show that tumor necrosis factor- α , IL-6, and IL-1 inhibitors are helpful for those who are indeed unresponsive to colchicines. The IL-1 blockers canakinumab and anakinra have been effective in clinical trials, decreasing the frequency and intensity of episodes of FMF flare-ups. The FDA approved the use of canakinumab (Ilaris) as a treatment for FMF in 2016.

Due to its nature as an inflammatory disease, anti-inflammatory pharmaceuticals such as NSAIDs, paracetamol, and dipyrrone are often utilized. Anti-inflammatory supplements such as curcumin, boswellia, and white willow

bark may also be helpful, as well as an anti-inflammatory diet that limits red meat, dairy, simple sugars, gluten, and processed foods.

Other medications may be used as needed to deal with the pain and fever associated with FMF attacks. Dialysis and/or renal transplant might become necessary in someone with advanced kidney disease. Given its genetic nature, there is no cure for FMF nor is there likely to be in the near future. Any couple that has a child diagnosed with FMF, or anyone with a family history of the condition (especially those in high-risk ethnic groups), should be offered genetic counseling to obtain the most up-to-date information on FMF and testing options.

Management of the genetic condition should also include surveillance via annual physical examination with urine spot tests and blood tests to ensure the provided treatment is indeed working and to ensure a rapid diagnosis of renal dysfunction should it occur.

Prognosis

For those individuals who are diagnosed early enough and take colchicine consistently, the prognosis is excellent. Most will have very few if any attacks of fever and polyserositis, and they will likely not develop serious complications of amyloidosis. The problem of misdiagnosing FMF continues, but education attempts directed at both the public and medical care providers should improve the situation. Future research should provide a better understanding of the inflammation process, focusing on how neutrophils are genetically regulated. That information could then be used to develop treatments for FMF with fewer side effects, and might also assist in developing therapies for other diseases in which abnormal inflammation and immune response are a problem.

Fanconi anemia

Definition

Fanconi anemia is an inherited disorder characterized by a severe form of anemia and various other physical malformations. Patients with Fanconi anemia are susceptible to various types of cancer.

Description

Fanconi anemia (FA) was first described in 1927 by a Swiss pediatrician named Guido Fanconi (1892–1979). It is also called Fanconi pancytopenia, constitutional aplastic anemia, and aplastic anemia with congenital anomalies. It is a rare inherited bone marrow failure syndrome or form of aplastic anemia. Aplastic anemia is a life-threatening condition in which a person is unable to produce adequate amounts of red blood cells, white blood cells, or platelets. Red blood cells serve to carry oxygen to all areas of the body. White blood cells help to fight infection and disease. Platelets are responsible for clotting to help to heal wounds and control bleeding. Without adequate amounts of these important blood cells, patients affected with aplastic anemia are easily fatigued and susceptible to infections. Most cases of aplastic anemia develop throughout the course of a person's lifetime. However, in FA, the aplastic anemia is congenital, or present from birth.

Fanconi anemia: pedigree analysis chart (Gale)

FA is associated with various other findings in about 60% of patients. These include low birth weight, short stature, skeletal abnormalities, skin discoloration, small eyes, infertility, kidney problems, and heart defects. Additionally, people with FA experience a high incidence of leukemia and an increased incidence of other types of cancer, usually solid tumors.

The chromosomes in the cells of FA patients break and rearrange easily. Chromosomes are the information manuals of our cells. Genes are arranged on chromosomes in a linear fashion like beads on a string. Genes tell cells how to make proteins. These proteins perform many vital functions in the body. When chromosomes break, genes are disrupted and do not function correctly. Mutations in the genes lead to the encoding of abnormal proteins and various health problems associated with the defective proteins. The chromosome breakage in FA can be seen in the laboratory and is used to diagnose the disorder.

Genetic profile

At least 21 different genes were associated with FA as of 2021. A mutation in any one of these genes may cause the disorder.

Inheritance patterns

With the exception of one gene associated with Fanconi anemia, FA is inherited in an autosomal recessive pattern. This inheritance pattern means that for someone to be affected with FA, each of their parents must have a mutation in the same gene. Parents who carry the defective gene do not show symptoms of FA because they have a corresponding gene on the other chromosome that produces an adequate amount of protein. Thus they often do not know they are carriers until they have an affected child. If both parents carry the same defective gene, each of their children has a 25% chance of inheriting both abnormal genes and being affected with FA. Likewise, each child has a 25% chance of inheriting two functional copies of the gene and being unaffected. This leaves a 50% chance that the offspring will have one functional gene and one defective gene and will be an unaffected carrier of the disorder.

The exception to this autosomal recessive inheritance pattern is FA resulting from mutations in the *FANCB* gene, which is located on the short arm of the X chromosome at Xp22.2. Mutations in this gene account for about 2% of FA cases, and are inherited in an X-linked recessive pattern. In this pattern, male offspring of a mother carrying the defective gene on one of her X chromosomes will develop

FA because they do not have a second normal copy of the X-linked gene. Daughters are not affected unless they inherit a defective X chromosome from the father as well as the defective X chromosome from the mother.

FA gene mutations and the FA pathway

The known FA genes are as follows: the *FANCA* gene on the long arm of chromosome 16 at 16q24.3; the *FANCB* gene on the short arm of the X chromosome at Xp22.2; the *FANCC* gene on the long arm of chromosome 9 at 9q22.3; the *FANCD2* gene on the short arm of chromosome 3 at 3p26; the *FANCE* gene on the short arm of chromosome 6 at 6p21.31; the *FANCF* gene on the short arm of chromosome 11 at 11p15; the *FANCG* gene on the short arm of chromosome 9 at 9p13; the *FANCI* gene on the long arm of chromosome 15 at 15q26.1; the *FANCL* gene on the short arm of chromosome 2 at 2p16.1; the *FANCM* gene on the long arm of chromosome 14 at 14q21.2; the *BRCA2* gene on the long arm of chromosome 13 at 13q12.3; the *BRIP1* gene on the long arm of chromosome 17 at 17q22.2; the *PALB2* gene on the short arm of chromosome 16 at 16p12.2; the *RAD51C* gene on the long arm of chromosome 17 at 17q22; the *SLX4* gene on the short arm of chromosome 16 at 16p13.3; the *ERCC4* gene on the short arm of chromosome 16 at 16p13.12; the *BRCA1* gene on the long arm of chromosome 17 at 43q44; the *XRCC2* gene on the long arm of chromosome 7 at 7q36.1; the *MAD2L2* gene on the short arm of chromosome 1 at 1p36.22; the *RFWF3* gene on the long arm of chromosome 16 at 16q23; and the *UBE2T* gene on the long arm of chromosome 1 at 1q32.1. Eighty to 90% of cases of FA are caused by mutations in just three of these genes, *FANCA*, *FANCC*, and *FANCG*, because of their crucial role in DNA repair.

To understand how these genes are involved in the pathogenesis of FA, it is important to have an outline of the process of DNA repair in people with FA. The *FANCA*, *FANCC*, and *FANCG* genes code for proteins that function in a DNA repair process called the FA pathway. This pathway is activated when the process of DNA replication (copying) is interrupted by DNA damage. The type of damage most likely to activate the FA pathway is known as interstrand cross-links, or ICLs. ICLs occur when two nucleotides (the “building blocks” of DNA) on opposite DNA strands form abnormal attachments called cross-links. The most common causes of ICLs are toxic substances that build up in the body and certain cancer chemotherapy drugs. The formation of ICLs stops the process of DNA replication.

The FA pathway is a process with several stages in which it directs repair proteins to the area damaged by an ICL so that the DNA can continue replicating. The three most important FA genes, *FANCA*, *FANCC*, and *FANCG*, contain instructions needed for producing a

group of eight proteins called the FA core complex, which in turn activates two proteins called FANCD2 and FANCI. These two proteins then attract DNA repair proteins to the portions of DNA affected by ICLs. The repair proteins remove the cross-links, allowing DNA replication to resume.

Mutations in any of the *FANCA*, *FANCC*, and *FANCG* genes will cause the FA core complex to lose its ability to function, thus blocking the entire FA pathway. As a result, the ICLs accumulate over time, the damaged DNA is not repaired, and DNA replication eventually stops. The end result is either an abnormally high rate of cell death resulting from the lack of new DNA molecules, or uncontrolled cell growth caused by the absence of DNA repair. In Fanconi anemia, a high rate of cell death leads to the low level of blood cells and physical deformities seen in the disorder, while uncontrolled cell growth leads to myelodysplastic syndromes and acute myeloid leukemia.

Demographics

FA occurs equally in males and females. The total number of FA patients has not been fully documented; only about 2,000 cases of FA have been reported in the medical literature since 1927. It has been estimated, however, that between 1 in 100 and 1 in 600 people carry one of the defective FA genes. According to the Cincinnati Children’s Hospital Medical Center, 31 babies with FA are born in the United States in an average year.

FA is found in all ethnic groups worldwide but is relatively frequent in the Ashkenazi Jewish population. One in every 89 people in this population carries a mutation in the *FANCC* gene. Other groups with higher than average rates of mutations in the FA genes include the Afrikaners (descendants of nineteenth-century Dutch settlers) of South Africa, black Africans from sub-Saharan Africa, and the Roma people living in Spain.

Signs and symptoms

The signs and symptoms of FA generally appear in children between the ages of 3 and 12. In rare cases, symptoms do not present until adulthood. These symptoms vary in severity from case to case. Even within the same family, siblings who are both affected may show very different signs of the disorder.

Aplastic anemia is the first sign of FA in many patients. In some cases, it may be the only sign of the disorder. In aplastic anemia, the bone marrow does not produce an adequate number of red cells, white cells, or platelets. Known as pancytopenia, this deficiency can lead to several conditions. Anemia can result from the lack of red blood cells, leading to weakness, fatigue, and

KEY TERMS

Acute myelogenous leukemia (AML)—A life-threatening disorder of the bone marrow in which a large number of abnormal white blood cells accumulates in the marrow and reduces the production of normal red and white blood cells and platelets. It is also called acute myeloid leukemia.

Androgens—Synthetic male hormones given to patients with FA to improve their blood cell counts. They are effective in about 50% of patients.

Aplastic anemia—A disorder in which the bone marrow and its blood stem cells are damaged such that it cannot produce mature red blood cells, white blood cells, or platelets.

Café-au-lait spots—Light brown birthmarks on the skin that are usually harmless but may be associated with Fanconi anemia and several other syndromes. The name is French and means “coffee with milk,” which describes the color of the spots.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Congenital—Present at birth.

DNA replication—The process in which a DNA molecule forms two identical copies of itself.

FA core complex—A group of eight proteins encoded by FA genes that function as part of the FA pathway in DNA repair. The FA core complex has been described as a cellular “machine” for DNA repair.

FA pathway—The biological process that is activated when DNA replication is shut down by interstrand cross-links and other types of DNA damage.

Myelodysplastic syndromes—Disorders of the bone marrow in which immature blood cells called myeloblasts increase in number and prevent the effective production and maturation of normal red and white blood cells and platelets. About a third of untreated myelodysplastic syndrome cases progress to acute myelogenous leukemia.

Pancytopenia—A medical condition characterized by abnormally low levels of all three types of blood cells: red blood cells, white blood cells, and platelets.

Pathogenesis—The biological mechanism that leads to a disease or disorder, or the origin and development of the disease.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Tumor—An abnormal growth of cells. Tumors may be benign (noncancerous) or malignant (cancerous).

a pale appearance. Without enough white blood cells, the patient may be vulnerable to common germs and infections. The deficiency in platelets can cause easy bruising, nosebleeds, and possible internal bleeding.

Ten to 15% of patients with FA develop leukemia, specifically acute myelogenous leukemia (AML). Leukemia is a cancer of the blood system in which abnormal white blood cells grow rapidly in number and suppress the development of healthy blood cells. AML is a particularly aggressive type of leukemia and is difficult to treat successfully. Individuals with FA are very sensitive to the toxic drugs used to fight leukemia, which makes treatment even more difficult.

Some patients with FA develop myelodysplastic syndromes (MDS), which may be precursors of AML. Myelodysplastic syndromes are disorders of the bone marrow in which the development of mature blood cells is disturbed. Instead of red and white blood cells and platelets maturing normally and in sufficient numbers, the number of myeloblasts (immature blood cells) increases and the number of mature blood cells drops. As a

myelodysplastic syndrome progresses, the myeloblasts increase to the point where they invade the bone marrow, further lowering the production of mature blood cells. When the abnormal myeloblasts account for 20% or more of cells in the bone marrow, the disorder is defined as having progressed to AML.

Among the physical defects associated with FA, short stature is very common. Additionally, an affected child may be born with missing, misshapen, or extra thumbs, or an underdeveloped or missing bone in the arm. Approximately one-fifth of patients with FA exhibit other skeletal abnormalities, such as malformations of the hip, spine, or rib. About 25% of individuals with FA are born with abnormalities of the kidneys. Some are born with defects of the heart, stomach, esophagus, or intestinal tract. These problems may require immediate surgery at birth.

FA is also associated with hyperpigmentation, or a darkening of the skin, in approximately 65% of patients. This darkening may be present in the form of spots known as *café-au-lait* spots, or it may be more diffuse

over a larger portion of the body. Additionally, the head or eyes may be smaller than average and some patients may not grow properly. Learning disabilities are thought to be fairly common in FA as well. Hearing loss has been reported in 10% of patients.

As these individuals become older, other problems may appear. In males, it is common to see underdeveloped male organs and infertility. Females often have a delay in the start of their menstrual periods and a decrease in fertility. Menopause in women with FA may occur as early as age 30.

People with FA, especially those over the age of 20, are at a high risk of developing malignant solid tumors in the head, neck, intestines, urinary tract, liver, and esophagus. Women are also at an increased risk of cancers in their reproductive organs; this risk is related to the fact that mutations in the *BRCA2* gene are associated with ovarian and breast cancer as well as Fanconi anemia.

Diagnosis

FA is often suspected in early childhood because of its characteristic physical deformities—particularly the thumb and arm abnormalities—and the development of aplastic anemia. However, the definitive diagnostic test for suspected FA is a laboratory test, called a chromosome breakage test. White blood cells are isolated from a patient's blood sample and destructive chemicals are added to these cells. The chemicals used most often for the test are diepoxybutane (DEB) and mitomycin C (MMC). The chromosomes are then viewed under a microscope. If the person is not affected with FA, the chromosomes will appear normal. If the person is affected with FA, the chromosomes will be broken and rearranged. Skin cells can be tested in a similar fashion and will often show this chromosome breakage as well. This particular test can be completed prenatally if a family desires to know whether a child is affected before he or she is born. Cells obtained from the mother's placenta or cells floating in the amniotic fluid that surrounds the fetus in the womb can be used to detect chromosome breakage.

Molecular genetic testing was available as of 2021 for all known FA genes. It is recommended that the siblings of a person diagnosed with FA be tested for mutations as well and that genetic counseling be offered to the entire family.

Treatment and management

Once the diagnosis of FA has been made, several initial tests should be completed, including liver and kidney function studies, a formal hearing evaluation, a

QUESTIONS TO ASK YOUR DOCTOR

- Which genes are involved?
- Is androgen therapy safe for girls and women with FA?
- What is the prognosis?
- Is bone marrow transplantation a possible treatment for the specific patient in my family?

developmental assessment, and an ultrasound examination of the kidneys and urinary system.

People affected with FA should be followed closely by a physician. Their blood cell and platelet counts should be monitored frequently. Symptoms caused by anemia and low platelet levels, such as bleeding, fatigue, chest pain, and dizziness, can be treated with transfusions as needed. Antibiotics are often given to fight infections. At times, hospitalization may be necessary to adequately tend to these complications. As patients get older, they should be monitored for any signs of solid tumors.

Due to either aplastic anemia or leukemia, many individuals with FA will eventually require a bone marrow transplant. The donor must be carefully matched to the patient. The prognosis for transplant is best for young patients who have a sibling donor with a matching tissue type. Bone marrow transplants, however, are not an option for many patients with FA because pre-treatment for these transplants requires chemotherapy and radiation therapy to prevent rejection of the transplant. Because FA makes some patients hypersensitive to chemotherapy and radiation treatment, bone marrow transplantation has a low rate of success in treating FA.

Between 50% and 75% of individuals with FA will respond to administration of androgens. These are artificial male hormones taken by mouth that can stimulate production of one or more types of blood cells. They are most effective in increasing the number of red blood cells but can increase the levels of platelets and white cells as well. These drugs prolong the lives of individuals with FA but are not a cure for the disorder. They also have side effects that include high blood pressure, headaches, nausea and vomiting, acne or oily skin, breast tenderness, and loss of menstruation in girls.

Various hematopoietic growth factors have been studied in relation to FA. These substances are already present in the body and serve to stimulate the production of blood cells and platelets. Scientists have developed a

way to manufacture these substances. They have been given to patients with FA and show promise in increasing the count of blood cells and platelets.

Prognosis

FA is an unpredictable illness. The average life expectancy for an affected individual was 30 to 33 years as of 2021, but any specific individual can have a life span above or below this average; some patients live into their 50s. Research discoveries have led to life-extending treatments and improved bone marrow transplant outcome. However, as patients live longer, they become at increased risk of developing other types of tumors. The most common causes of death in FA are bone marrow failure, leukemia, or solid tumors.

Fanconi-Bickel syndrome

Definition

Fanconi-Bickel syndrome (FBS) is a rare inherited disorder of carbohydrate metabolism caused by mutations in the gene known as *GLUT2*.

Description

Also known as glycogen storage disease type XI, the disease was first described by scientists G. Fanconi and Horst Bickel in 1949. Since then, only a few dozen cases of FBS have been studied—most in the United States, Europe, and Japan.

Onset of FBS is within the first year of life, with the overt symptom being a failure to thrive. At age two, an enlarged liver and kidneys are present and the child has rickets. The incidence of FBS has not been determined, but it is believed to occur in less than one in one million births.

Genetic profile

Fanconi-Bickel syndrome is believed to be an autosomal recessive disorder. This means that an individual with FBS would have to inherit an abnormal copy of the gene from both parents in order to show symptoms of FBS. People with only one abnormal gene are carriers and do not have the disorder. When both parents have the abnormal gene, there is a 25% chance with each birth that their child will inherit both abnormal genes and have the disease. There is a 50% chance with each birth that the child will inherit one abnormal gene and become a carrier of the disorder but not have the disease itself. There is a 25% chance each child will neither

KEY TERMS

Carbohydrate—Any of various natural compounds of carbon, hydrogen, and oxygen (as in sugars and starches) that are burned by the body for energy.

Diabetes mellitus—The clinical name for common diabetes. It is a chronic disease characterized by inadequate production or use of insulin.

Hyperlordosis—An exaggerated curve in the lower (lumbar) portion of the back.

Osteoporosis—Loss of bone density that can increase the risk of fractures.

Pancreas—An organ located in the abdomen that secretes pancreatic juices for digestion and hormones for maintaining blood sugar levels.

Pancreatitis—Inflammation of the pancreas.

Rickets—A childhood disease caused by vitamin D deficiency, resulting in soft and malformed bones.

inherit the abnormal gene and not have the disease nor be a carrier.

Demographics

Since there is so little research on Fanconi-Bickel syndrome, no clear pattern of demographics has been established. However, the disorder is known to affect both males and females. One common thread in some of the cases that have been studied has been consanguinity, meaning that FBS is found in the children of two persons of the same blood relation. In several of these cases the consanguinity is between two first cousins.

Signs and symptoms

In a 1987 study by researchers at the Research Institute for Child Nutrition in Dortmund, Germany, nine cases of Fanconi-Bickel syndrome were compared for clinical symptoms, behavior symptoms, and physical appearance. The initial symptoms reported were fever, vomiting, growth failure, and rickets between the ages of three and ten months. Later, these same patients showed signs of dwarfism, a protruding abdomen, enlarged liver, moon-shaped face, and abnormal fat deposits around the shoulders and abdomen. Also, cutting of teeth and puberty were delayed. Complications present included fractures and pancreatitis (an enlarged pancreas). Later in life, rickets and osteoporosis were constant features.

QUESTIONS TO ASK YOUR DOCTOR

- What is the genetic mechanism by which Fanconi-Bickel syndrome is inherited?
- At what age is the disorder normally manifested, and how is it originally diagnosed?
- How does the lifespan of a child with Fanconi-Bickel syndrome compared to a child in normal health?
- Are there books, pamphlets, or other written material to which I can turn for additional information about Fanconi-Bickel syndrome?

The German study, whose researchers included H. Bickel, co-discoverer of the syndrome, also used ultrasound to determine increased kidney size and growth in relation to body height. The most prominent finding was glucosuria (glucose, or sugar, in the urine). Polyuria (increased urination) was also a constant finding. The study noted that liver size was normal or slightly increased at birth in all nine cases but became greatly enlarged during infancy. The liver size and glycogen (a glucose storage molecule) content were reduced when the patients were placed on an antiketogenic (high carbohydrate) diet.

Other laboratory findings included fasting hypoglycemia (low levels of sugar in the blood), ketonuria (high levels of ketones in the urine), high hypercholesterolemia (high cholesterol), hypophosphatemia (high phosphate levels in the blood), and high levels of amino acids and protein in the urine. In a 1995 study at Children's Hospital in Philadelphia of an eight-year-old with Fanconi-Bickel syndrome, doctors reported additional symptoms of overworked kidneys, very small amounts of albumin (a class of water-soluble proteins) in the urine, and an increase in the number of cells in the inner part of the kidney that filters blood.

Diagnosis

Fanconi-Bickel syndrome can usually be identified in patients by neonatal screening for galactose, a type of sugar. Patients with FBS are intolerant of galactose. Other diagnostic factors include an impaired glucose tolerance test; x-ray to determine the pattern of rickets; urine tests to measure levels of glycose, phosphates, amino acids, and bicarbonate; and a liver biopsy to detect abnormal galactose oxidation.

Treatment and management

There is no effective treatment for Fanconi-Bickel syndrome. However, some of the symptoms can be treated with adequate supplementation of water, electrolytes, and vitamin D; restriction of galactose; and a diabetes mellitus-like diet (low sugar and low carbohydrate) presented in frequent small meals. These treatments can improve growth and give the patient a general sense of well-being.

Prognosis

The long-term prognosis has not been determined. It may depend on the severity of symptoms and early diagnosis and treatment of symptoms. The first person diagnosed with the disorder in 1949 was a four-year-old Swiss boy with consanguineous parents. At six months, the boy had excessive thirst, constipation, and was not thriving. He was treated with vitamin D and calcium supplements. At about age four, the boy had short stature, a protruding abdomen, an enlarged liver, facial obesity, osteopenia, and hyperlordosis. At age 12, the boy was found to be resistant to glycogen. In 1997 at age 52, the patient, without any treatment other than vitamin D and calcium supplements, was of short stature (4 ft. 8 in., 140 cm), weighed about 95 lb. (43 kg), had a moderately protruding abdomen, and a smaller than normal liver. Other than arthritis, he had no medical complaints. However, other people diagnosed as children with FBS had much shorter life spans. Long-term follow-up studies of nine persons with FBS showed severely retarded growth, partly compensated for by late onset of puberty.

Feingold syndrome

Definition

Feingold syndrome, previously known as oculo-digito-esophageal-duodenal syndrome (ODED), is a rare genetic disorder characterized by multiple conditions including various hand and foot abnormalities, small head (microcephaly), incompletely formed esophagus and small intestine (esophageal/duodenal atresia), an extra eye fold (short palpebral fissures), and learning disabilities.

Description

Individuals diagnosed with Feingold syndrome usually have a small head (microcephaly), fused toes (syndactyly), shortened fingers (mesobrachyphalangy), permanently outwardly curved fingers (clinodactyly), an extra eyelid fold (palpebral fissures), and learning delays. Other features can include backbone abnormalities (vertebral anomalies), an opening between the esophagus and the windpipe (tracheoesophageal fistula), and/or an incompletely formed esophagus or intestines (esophageal or duodenal atresia). The syndrome was first described by Dr. Murray Feingold in 1975. The underlying cause of the different features of Feingold syndrome is not fully understood. Feingold syndrome is also known as microcephaly mesobrachyphalangy tracheoesophageal fistula syndrome (MMT syndrome), and microcephaly-oculo-digito-esophageal-duodenal (MODED) syndrome.

KEY TERMS

Contiguous gene syndrome—A genetic syndrome caused by the deletion of two or more genes located next to each other.

Variable penetrance—A term describing the way in which the same mutated gene can cause symptoms of different severity and type within the same family.

Genetic profile

The genetic cause of Feingold syndrome is still being investigated. As of 2021, studies had identified alteration of the *MYCN* gene as causing this syndrome. This gene mutation has been linked to 47% of the cases of Feingold syndrome. The *MYCN* gene is located on the short arm of chromosome 2 and plays a major role in the development of structural tissue and organs during embryonic development. If this gene is mutated, these tissues and organs will not develop properly, leading to the signs and symptoms of this syndrome. However, it is still not clear if the features of Feingold syndrome are caused by a single mutation in one gene or the deletion of several side-by-side genes (contiguous genes).

This syndrome has also been linked to microdeletions in the *MIR17HG* gene on the long arm of chromosome 13 at 13q31, which encodes a micro RNA cluster known as miR-17/92. Some researchers refer to this form of the syndrome as Feingold syndrome type 2. As of 2021, about 25 patients worldwide have been identified with this type of Feingold syndrome.

Although the specific location and cause of Feingold syndrome is not fully determined, it is known that this syndrome is inherited in families through a specific autosomal dominant pattern. Every individual has approximately 30,000–35,000 genes that tell his or her body how to form and function. Each gene is present in pairs, with one inherited from the mother and one inherited from the father. In an autosomal dominant condition, only one nonworking copy of the gene for a particular condition is necessary for a person to experience symptoms of the condition. If a parent has an autosomal dominant condition, there is a 50% chance for each child to have the same or similar condition. Thus, individuals inheriting the same nonworking gene in the same family can have very different symptoms. For example, approximately 28% of individuals affected by Feingold syndrome have esophageal or duodenal atresia, while hand anomalies are present in almost 100% of affected individuals. The difference in physical findings within the same family is known as variable penetrance or intrafamilial variability.

Demographics

Feingold syndrome is a rare genetic condition. As of 2021, approximately 120 patients affected by Feingold syndrome had been reported in the literature. However, scientists believe that the syndrome has not been diagnosed in many affected individuals and suggest that it is more common than previously thought. The ethnic origin of individuals affected by Feingold syndrome is varied and is not specific to any one country or group.

Signs and symptoms

The signs and symptoms of Feingold syndrome vary from individual to individual. Most (86%–94%) individuals diagnosed with Feingold syndrome have a small head (microcephaly) and finger anomalies such as shortened fingers (mesobrachyphalangy), permanently curved fingers (clinodactyly), and/or missing fingers. Over half of affected individuals also have fused toes (syndactyly). Between 45% and 85% of individuals affected by Feingold syndrome have developmental delays and/or intellectual disability. Other features can include an extra eyelid fold (palpebral fissures), ear abnormalities/hearing loss, kidney abnormalities, backbone abnormalities (vertebral anomalies), an opening between the esophagus and the windpipe (tracheoesophageal fistula), and/or an incompletely formed esophagus or intestines (duodenal atresia seen in 20%–30%).

Diagnosis

Diagnosis of Feingold syndrome is usually made following a physical exam by a medical geneticist using x-rays of the hands, feet, and back.

Prenatal diagnosis of Feingold syndrome can sometimes be made using serial, targeted level II ultrasound imaging, a technique that can provide pictures of the fetal head size, hands, feet, and digestive tract. Ultrasound results indicative of Feingold syndrome include a “double bubble” sign suggesting incompletely formed intestines (duodenal atresia) and small head size (microcephaly). Diagnosis by ultrasound before the baby is born is difficult. Prenatal molecular genetic testing is available for those individuals who have a familial history with the syndrome.

Treatment and management

Since Feingold syndrome is a genetic disorder, no specific treatment is available to remove, cure, or fix all conditions associated with it. Treatment for Feingold syndrome is mainly limited to the treatment of specific symptoms. Individuals with incompletely formed intestinal and esophageal tracts require immediate surgery to try to extend and open the digestive tract. Individuals with learning difficulties or intellectual disability may benefit from special schooling and early intervention programs to help them learn and reach their potential.

QUESTIONS TO ASK YOUR DOCTOR

- What information is available about the genetic basis of this disorder?
- At what stage in fetal or postnatal development is it possible to diagnose Feingold syndrome, and on what is that diagnosis based?
- Are there currently any ongoing studies researching treatments for this genetic disorder and, if so, what results have they produced thus far?

Prognosis

Feingold syndrome results in a variety of different physical and mental signs and symptoms. Accordingly, the prognosis for each affected individual is very different.

Individuals who are affected by physical hand, head, or foot anomalies (with no other physical or mental abnormalities) have an excellent prognosis, and most live normal lives.

Babies affected by ODED who have incomplete esophageal or intestinal tracts will have many surgeries, and prognosis depends on the severity of the defect and survival of the surgeries.

Fetal alcohol spectrum disorders

Definition

Prenatal exposure to alcohol can cause a broad range of disorders, together known as fetal alcohol spectrum disorders (FASD). FASD includes four categories of diagnoses, including fetal alcohol syndrome (FAS), partial FAS (pFAS), alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defects (ARBD). In addition, the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes the diagnosis of neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE). A person who meets the criteria for an FASD diagnosis will also fulfill the criteria for ND-PAE, according to the National Institute of Alcohol Abuse and Alcoholism (NIAAA). The most severe effects of drinking during pregnancy occur with fetal alcohol syndrome (FAS), a pattern of birth defects and learning and behavioral problems affecting individuals whose mothers consumed alcohol during pregnancy. The NIAAA notes that a study of more than 6,000 children in first grade in the United States found that from 1% to 5% of children in first grade have fetal alcohol spectrum disorders (FASDs). Sometimes, children whose parents are alcohol abusers are placed in foster care, and some of these children have FASD. In 2019, 16% of children newly placed in the foster care system by child protective services in the United States had parents with an identified alcohol issue.

FASD has lifelong effects. In a study of more than 3,000 subjects between 2003 and 2013, Sarah Soyeon Oh and colleagues found that people with FASD have a 52 times greater risk for being hospitalized for diseases of the nervous system.

Description

FAS is the most common preventable cause of intellectual disability. This condition was first recognized and reported in the medical literature in 1968 in France and in 1973 in the United States. Alcohol is a teratogen, the term used for any drug, chemical, maternal disease, or other environmental exposure that can cause birth defects or functional impairment in a developing fetus. For this reason, doctors advise against drinking any alcohol during

pregnancy. Some features of FASD may be present at birth, including low birth weight, prematurity, and microcephaly (small head). Characteristic facial features may be present at birth or may become more obvious over time. Signs of brain damage include delays in development, behavioral abnormalities, and intellectual disability, but affected individuals exhibit a wide range of abilities and disabilities. It has only been since 1991 that the long-term outcome of FASD has been known. Learning, behavioral, and emotional problems are common in adolescents and adults with FAS.

Genetic profile

According to author Nina Kaminen-Ahola, FASD is partly a genetic disorder in that alcohol causes rearrangements and changes to the child's chromosomes while in utero. There are also gene-environment interactions to the fetus caused by the use of alcohol during pregnancy. Not all individuals from alcohol-exposed pregnancies have obvious signs or symptoms of FAS; individuals of different genetic backgrounds may be more or less susceptible to the damage that alcohol can cause. The dose of alcohol, the time during pregnancy that alcohol is used, and the pattern of alcohol use all contribute to the different signs and symptoms that are found in the child.

Demographics

There is no racial or ethnic predilection for FAS. Individuals from different genetic backgrounds who are exposed to similar amounts of alcohol during pregnancy may show different symptoms of FAS. The reported rates of FAS vary widely and depend on the population studied and the monitoring methods used.

Signs and symptoms

Classic features of FAS include short stature, low birth weight and poor weight gain, an abnormally small head (microcephaly), and a characteristic pattern of facial features. In infants and children, these may include small eye openings (measured from inner corner to outer corner), epicanthal folds (folds of tissue at the inner corner of the eye), small or short nose, low or flat nasal bridge, smooth or poorly developed philtrum (the area of the upper lip above the colored part of the lip and below the nose), thin upper lip, and small chin. Some of these features are nonspecific, meaning that they can occur in other conditions or be appropriate for age, racial, or family background. Other major and minor birth defects that have been reported include cleft palate, congenital heart defects, strabismus, hearing loss, defects of the spine and joints, alteration of the hand creases, and small fingernails and toenails. Since FAS was first described in infants and children, the disorder is sometimes more difficult to recognize in older adolescents and adults. Short stature and microcephaly remain common features, but weight may normalize, and the individual may actually become overweight for his or her height. The chin and nose grow proportionately more than the middle part of the face, and dental crowding may become a problem. The small eye openings and the appearance of the upper lip and philtrum may continue to be characteristic. Pubertal changes typically occur at the normal time.

Newborns with FAS may have difficulties with feeding due to sucking difficulties, irregular sleep-wake cycles, decreased or increased muscle tone, or seizures or tremors. Delays in achieving developmental milestones, such as rolling over, crawling, walking, and talking, may become apparent in infancy. Behavior and learning difficulties typical in the preschool or early school years include poor attention span, hyperactivity, poor motor skills, and slow language development. Attention deficit-hyperactivity disorder is a common associated diagnosis. Learning disabilities or intellectual disability may be diagnosed during this time. Arithmetic is often the most difficult subject for a child with FAS. During middle-school and high-school years the behavioral difficulties and learning difficulties can be significant. Memory problems, poor judgment, difficulties with daily living skills, difficulties with abstract reasoning skills, and poor social skills are often apparent by this time. It is important to note that animal and human studies have shown that neurologic and behavioral abnormalities can be present without characteristic facial features. These individuals might not be identified as having FAS but might fulfill criteria for alcohol-related diagnoses as set forth by the Institute of Medicine.

KEY TERMS

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Congenital—Refers to a disorder that is present at birth.

IQ—Abbreviation for "intelligence quotient." Compares an individual's mental age to his or her true or chronological age and multiplies that ratio by 100.

Microcephaly—An abnormally small head.

Miscarriage—Spontaneous pregnancy loss.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Strabismus—An improper muscle balance of the ocular muscles, resulting in crossed or divergent eyes.

Teratogen—Any drug, chemical, maternal disease, or exposure that can cause physical or functional defects in an exposed embryo or fetus.

In 1991, Streissguth and others reported some of the first long-term follow-up studies of adolescents and adults with FAS. In the approximately 60 individuals they studied, the average IQ was 68, with 70 being the lower limit of the normal range. However, the range of IQ was quite large, as low as 20 (severely intellectually disabled) to as high as 105 (normal). The average achievement levels for reading, spelling, and arithmetic were fourth grade, third grade, and second grade, respectively. The Vineland Adaptive Behavior Scale was used to measure adaptive functioning in these individuals. The composite score for this group showed functioning at the level of a seven-year-old. Daily living skills were at a level of nine years, and social skills were at the level of a six-year-old.

In 1996, Streissguth and others published further data regarding the disabilities in children, adolescents, and adults with FAS. Secondary disabilities, that is, those disabilities not present at birth and that might be preventable with proper diagnosis, treatment, and intervention, were described. These secondary disabilities included: mental health problems; disrupted school experiences; trouble with the law; incarceration for mental health problems, drug abuse, or criminal acts; inappropriate sexual behavior; alcohol and drug abuse; problems with employment; dependent living; and difficulties

parenting their own children. In that study, only seven out of 90 adults were living and working independently and successfully. In addition to the studies by Streissguth, several authors in various countries have now reported on long-term outcomes of individuals diagnosed with FAS. In general, the neurological, behavioral, and emotional disorders become the most problematic for the individuals. The physical features change over time, sometimes making the correct diagnosis more difficult in older individuals, without old photographs and other historical data to review. Mental health problems, including attention deficit, depression, panic attacks, psychosis, and suicide threats and attempts, were present in over 90% of the individuals studied by Streissguth.

Diagnosis

FAS is a clinical diagnosis, which means that there is no blood, x-ray, or psychological test that can be performed to confirm the suspected diagnosis. The diagnosis is made based on the history of maternal alcohol use and a detailed physical examination for the characteristic major and minor birth defects and characteristic facial features. It is often helpful to examine the siblings and parents of an individual suspected of having FAS, either in person or by photographs, to determine whether findings on the examination might be familial or whether other siblings may also be affected. Sometimes, genetic tests are performed to rule out other conditions that may present with developmental delay or birth defects. Individuals with developmental delay, birth defects, or other unusual features are often referred to a clinical geneticist, developmental pediatrician, or neurologist for evaluation and diagnosis of FAS. Psychoeducational testing to determine IQ and/or the presence of learning disabilities may also be part of the evaluation process.

Treatment and management

Most of the birth defects associated with prenatal alcohol exposure are correctable with surgery. Children should have a psychoeducational evaluation to help plan appropriate educational interventions. Common associated diagnoses such as attention deficit-hyperactivity disorder (ADHD), depression, or anxiety should be recognized and treated appropriately. The disabilities that present during childhood persist into adult life. However, some of the secondary disabilities may be avoided or lessened by early and correct diagnosis, better understanding of the lifelong complications of FAS, and intervention. According to the Centers for Disease Control and Prevention (CDC), early intervention as soon as possible is best, such as from birth to age three. The younger or older child may also benefit from speech therapy and physical therapy. Medications such as

QUESTIONS TO ASK YOUR DOCTOR

- My spouse and I plan to adopt a baby from foster care who may have fetal alcohol syndrome. What medical problems should we expect to develop as a result of this condition?
- What types of treatments are available for fetal alcohol syndrome?
- Is there a way of knowing what the long-term prognosis will be for a child with FAS?
- Is fetal alcohol syndrome a condition that can be transmitted genetically?

stimulants may help with hyperactivity, and antipsychotics may be used for anxiety, aggression, or other problematic behaviors.

The CDC, through a collaborative effort, seeks to identify, develop, and evaluate effective strategies for intervening with children with FAS and their families. Through these interventions, researchers are trying to help children with FAS develop their full potential, prevent secondary conditions, and provide education and support to caregivers and families. Some possibly hopeful findings were revealed in a study by Jeffrey R. Wozniak and colleagues, of children with FASD who were administered choline, a dietary supplement. In this study of 31 children with FASD, 15 were given choline, and 16 were given a placebo. Four years later, at age nine, the children who had been given the choline had a significantly higher non-verbal intelligence, as well as significant improvements in their visual-spatial skills, working memory, and verbal memory. The treated children also had fewer behavior symptoms of ADHD. Further research is needed to determine whether choline supplementation is effective in children with FASD.

Clinical trials

Clinical trials on FAS and FASDs are also currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2021, NIH reported 17 ongoing or completed studies.

A few examples include the following:

- An assessment of the effectiveness of an attachment-focused intervention for preschool children with FAS. (NCT01536184)
- A study to determine whether atomoxetine hydrochloride improves inattention, hyperactivity, and impulsivity

problems in children exposed to alcohol during birth. (NCT00417794)

- An evaluation of the types of parenting training that will most benefit children with FAS. (NCT02210455)

Clinical trial information is constantly updated by NIH (<http://clinicaltrials.gov>).

Prognosis

The prognosis for FAS depends on the severity of the defects and the level of brain damage present at birth. Miscarriage, stillbirth, or death in the first few weeks of life may occur in very severe cases. Major birth defects associated with FAS are usually treatable with surgery. Some of the factors that have been found to reduce the risk of secondary disabilities in FAS individuals include diagnosis before age six, stable and nurturing home environments, never having experienced personal violence, and referral and eligibility for disability services. In a study in Canada of individuals with FASD with a mean age of 16, researchers Svetlana Popova and colleagues found a high level of psychological and developmental disabilities (78%) in the subjects, as well as substance use (50%), and also involvement in the child welfare system (75%) and the criminal justice system (30%). Subjects older than age 20 had the greatest percentage of past alcohol use (39%). The researchers also found that 78% had mental health issues. The long-term data helps in understanding the difficulties that individuals with FAS encounter throughout their lifetimes and can help families, caregivers, and professionals provide the care, supervision, education, and treatment geared toward their special needs.

Prevention of FAS is the key. Prevention efforts must include public education efforts aimed at the entire population (not just at women of child-bearing age); appropriate treatment for women with high-risk drinking habits; and increased recognition and knowledge about FAS by professionals, parents, and caregivers. All FASDs are 100% preventable if a woman does not drink alcohol while she is pregnant.

FG syndrome

Definition

FG syndrome (FGS) is a genetic disorder characterized by intellectual disability, low muscle tone (hypotonia), enlarged cranium, constipation, and anal abnormalities.

Description

FGS refers to a rare genetic condition that has a variety of physical and mental symptoms. Most individuals affected by FGS have symptoms including intellectual disability, low muscle tone, brain abnormalities (partial agenesis of the corpus callosum), seizures, large head, characteristic facial features, large intestinal and anal abnormalities, constipation, short stature, joints that tend to stay in one place (fixed), broad big toes, and light and dark skin streaking. The syndrome was first described by Opitz and Kaveggia in 1974 based on physical findings and family history. All of these features appear to be caused by mutated or changed genes on the X chromosome. Although the full effect of the mutation or change in the gene is not fully understood, the mutations are believed to interrupt the genes' normal functions in the brain, digestive tract, and muscle tissue.

Other names for FGS include Opitz-Kaveggia syndrome and Keller syndrome.

Genetic profile

FGS is caused by mutations on the long arm of the X chromosome. Studies in 1998 and 2000 found that individuals affected by FGS can have a mutation on the X chromosome in two different locations on the long arm (q) of the X chromosome: Xq12-Xq21 (called FGS1) and Xq28 (called FGS2). When a set of symptoms are caused by gene mutations at different locations, the disorder is called heterogeneous. Although a gene mutation causing FGS can appear in an individual for the first time without being found in the affected individual's parents, most cases of FGS are inherited.

Since both possible gene mutations are found on the X chromosome, FGS is inherited in an X-linked recessive pattern. Every individual has approximately 30,000–35,000 genes that tell his or her body how to form and function. Each gene is present in pairs, with one inherited from the mother and one inherited from the father. Females have two X chromosomes, while males have a single X chromosome and Y chromosome. In other words, females receive two copies of the genetic information stored on the X chromosome. When a female inherits the gene for an X-linked recessive condition, she is known as a carrier. She usually has no problems related to that condition because the gene on her other X chromosome continues to function properly and "masks" the

abnormal gene. However, males inherit only one copy of the information stored on the X chromosome. When a male inherits the gene for an X-linked recessive condition, he will experience the symptoms associated with that condition. The mutated or changed genes that cause FGS are located on the X chromosome; thus, the full-blown disorder primarily affects males carrying the mutated or changed gene on their one X chromosome. When a condition is X-linked, the gene for the condition travels through the family on the X chromosome. In X-linked genetic conditions, the risk for a carrier female to have an affected son is 50%, while the risk to have a carrier daughter is also 50%. An affected male has a 100% chance of having carrier daughters and no chance to have an affected son.

Individuals inheriting the same mutated gene in the same family can have very different symptoms. For example, approximately 38% of individuals affected by FGS have anal anomalies, like a missing anal opening (imperforate anus), while intellectual disability is present in 97% of individuals affected by FGS. The difference in physical findings within the same family is known as variable penetrance or intrafamilial variability.

As of 2013, studies had pointed out a possible genetic link between the *MED-12* gene and FGS. The *MED-12* gene is a member of a larger complex that plays a role in cell growth and differentiation. It is also a suppressor for other genes such as *SHH*, which plays a role in the timing of cell growth. If this gene is not translated or transcribed correctly, growth abnormalities will occur during the embryonic stage. Studies have concluded that a possible missense mutation or a frameshift mutation of this gene directly leads to FGS as well as other intellectual disability and growth abnormality syndromes such as Lujan syndrome and Ohdo syndrome. Other X-linked genes known as of 2021 to be involved in the spectrum of FG signs and symptoms include *FLNA*, *BRWD3*, *FMRI*, *CASK*, *MECP2*, *ATRX* and *UPF3B*.

Demographics

FGS can appear in any ethnic population. It has been described in individuals of Japanese, American, European,

African, and other ethnic backgrounds. FGS is not believed to be more common in one specific population. The prevalence of FGS is not currently known, although several hundred cases have been reported throughout the world. This information may be skewed, however, due to the similarities of FGS and other disorders.

Signs and symptoms

Individuals affected by FGS can be affected by a variety of symptoms. Most affected individuals have signs of FGS such as intellectual disability, low muscle tone and physical development, seizures, large heads, big foreheads, a front cowlick of hair, wide-spaced eyes, extra eye folds (short, palpebral fissures), constipation, and an outgoing, talkative personality. Other fairly common signs of FGS include anal abnormalities (imperforate anus), brain abnormalities (partial agenesis of the corpus callosum), hearing impairments, broad thumbs and big toes, small ears, fine/thinning hair, fused fingers, minor backbone abnormalities, cleft lip and palate, heart defects, and fetal fingertip pads.

Diagnosis

Diagnosis of FGS is usually made from physical examination by a medical geneticist. The physical examination looks for the combined characteristic features, low muscle tone, intellectual disability, and other related signs and symptoms. Genetic testing for mutations in the *MED12* gene is also available as of 2021. Diagnostic criteria to differentiate FGS from Lujan syndrome (LS) have been developed. Although FGS and LS share similar characteristics such as intellectual disability, muscle weakness, and brain abnormalities, FGS can be clinically differentiated from LS by its characteristic facial features and digestive tract dysmorphia, whereas LS syndrome has a separate set of characteristic facial features without digestive tract dysmorphia.

Treatment and management

FGS is a genetic disorder and does not have a specific therapy that removes, cures, or fixes all signs of the disorder.

Management and treatment for FGS mainly focuses on the treatment of specific symptoms. More specifically, individuals with incompletely formed anal openings and serious heart defects would need surgery to try to correct the problems. Individuals affected by FGS who have intellectual disability benefit from special schools and early intervention programs.

Prognosis

The prognosis of an individual affected by FGS depends on the severity of the symptoms by which he or she is affected. For example, approximately one-third of

Fibroblast growth factor receptor-related conditions

Definition

Fibroblast growth factor receptors (FGFRs) are a family of proteins involved in cell division, growth, maturation, differentiation, and healing. These receptors receive signals from other proteins outside the cell wall called fibroblast growth factors (FGFs). In humans and other mammals, fibroblast growth factors are important in the development of muscle tissue, limb growth and lengthening, blood vessel development, craniofacial development, and cell specialization.

When an FGF protein attaches to a fibroblast growth factor receptor, the receptor initiates a series of chemical reactions inside the cell that enable the cell to mature, to take on specialized functions, or to undergo certain other changes. Mutations in the genes that code for fibroblast growth factor receptors lead to various genetic disorders marked by short stature, premature fusion of the bones of the skull, craniofacial anomalies, and the speeded-up progression of certain types of cancers. There are four known genes that code for FGFRs: *FGFR1*, *FGFR2*, *FGFR3*, and *FGFR4*.

Description

Fibroblast growth factor receptors

Fibroblast growth factor receptors (FGFRs) are a family of proteins that play critical roles in cell division, maturation, and specialization, as well as the formation of blood vessels (angiogenesis) and embryonic development. As a group, FGFRs are very similar to each other in their structure and function. All are transmembrane proteins composed of three distinct parts: a binding site on the exterior of the cell membrane, an active site on the interior of the cell membrane, and a connecting section spanning the cell membrane and joining the inner and outer components.

Fibroblast growth factors (FGFs) attach to the binding site of the extracellular portion of the FGFR protein. As of 2021, there were at least 23 known human FGFs, ten of which bind to and interact with FGFRs. Two FGFs must first bind with each other; as a pair, they fit into the FGFR binding site, forming an FGF/FGFR complex. FGF pairing and FGF/FGFR binding is non-specific, with any two FGFs coupling and binding any FGFR.

When the binding site is empty and no FGF is bound, the FGFR is inactive and cellular growth continues unchecked. When an FGF pair binds, the FGF/FGFR complex sends a signal that travels the length of the

FGFR-related dwarfism syndromes (Gale)

FGFR protein, resulting in the stimulation of the active site on the inside of the cell membrane.

The active site of the FGFR stimulates molecules within the cell through the biochemical process of phosphorylation. Each activated molecule goes on to affect another molecule, thereby propagating the original signal and, much like the domino effect, triggering a cascade of events. The process continues, molecule by molecule, until the signal reaches the nucleus of the cell, ultimately resulting in the inhibition of cell growth.

FGFR genes

A different *FGFR* gene codes for each of the four types of FGFR proteins (Table 1). Genes are the genetic material passed down from generation to generation that tells a person's body how to work and how to grow. Genes are packaged into chromosomes, with hundreds of genes on each chromosome. Individual cells contain 46 chromosomes, which may be matched into 23 pairs. One of each pair is inherited from the egg of the mother, and one of each pair is inherited from the sperm of the father.

A mutation—a change in an *FGFR* gene—also changes the structure of the FGFR protein, which then affects the protein's function. Most *FGFR* gene mutations are thought to cause the protein receptors to become overly active. These defective receptors stimulate the activation cascade independent of FGF binding. This process causes a strong slowing-down effect on growth, which is readily observed in the symptoms of affected individuals. Common features of the disease include abnormalities of the limbs, skin, head, and face.

Other mutations in FGFR genes are associated with certain cancers, resulting in uncontrolled cell division, speeding up tumor growth, and the formation of new blood vessels that feed cancerous tumors.

FGFR1	8p11	FGFR1
FGFR2	10q26	FGFR2
FGFR3	4p16	FGFR3
FGFR4	5q35	FGFR4

FGFR Genes (Gale)

The four FGFR genes in humans are *FGFR1*, located on the short arm of chromosome 8 at 8p11.23-p11.22; *FGFR2*, located on the long arm of chromosome 10 at 10q26; *FGFR3*, located on the short arm of chromosome 4 at 4p16.3; and the *FGFR4* gene, located on the long arm of chromosome 5 at 5q35.2.

Inheritance patterns

FGFR-related syndromes are inherited in an autosomal dominant pattern. That is, although individuals inherit two copies of each FGFR gene, only one copy must be mutated for a person to be affected with a disorder. Some individuals with an FGFR-related disorder have a parent affected by the same disease, in which case the disease is said to be familial. Other individuals are the first person in their family to be affected. These cases are considered sporadic, meaning they arose from a new mutation in the affected person's DNA.

Whether familial or sporadic, all affected individuals have a 50% chance of passing on the disease to a child in any future pregnancy. The overall risk for the offspring can change if an affected person has a child with an individual affected by the same disease.

Genetic testing

Prenatal testing is available for all of the FGFR-associated syndromes. Some cases are diagnosed based on clinical presentation, while others are diagnosed by DNA

mutation analysis. Chorionic villus sampling (CVS) or amniocentesis may be used when there is a known familial mutation. If there is no family history of FGFR-related disease, but prenatal examination by ultrasound gives rise to concern, prognosis and diagnosis are traditionally based on clinical findings after birth.

A newer and less invasive method of prenatal genetic testing involves analysis of cell-free DNA in maternal blood; this method has been used successfully to test for achondroplasia and thanatophoric dysplasia. Molecular genetic testing is available for mutations in all four *FGFR* genes.

Diseases related to *FGFR* genes

Genetic disorders associated with *FGFR* genes fall into several major categories: craniosynostoses, which are disorders in which the child’s skull is misshapen due to abnormally early closure of the cranial sutures; dwarfism syndromes; and certain types of cancer.

FGFR1-related conditions

The *FGFR1* gene is thought to have important functions in the development of the fetus’s nervous system as well as controlling the growth of the long bones in the arms and legs. Mutations in this gene are linked to the following disorders:

- Kallmann syndrome type 2, also known as isolated gonadotropin-releasing hormone (GnRH) deficiency (IGD). Kallmann syndrome (KS) is a rare disorder with several different inheritance patterns marked by failure to begin or fully complete puberty as a result of impaired secretion of gonadotropins—hormones necessary for normal growth and sexual development. About 50% of patients diagnosed with KS have a diminished (hyposmia) or completely absent sense of smell (anosmia). The role of the *FGFR1* gene in KS type 2 is evident in the autosomal dominant pattern of inheritance and the fact that children with this subtype of KS frequently have malformations of

the hands, such orofacial abnormalities as cleft palate, and dental agenesis (failure of some or all permanent teeth to develop)—features that do not appear in other subtypes of KS. Mutations in the *FGFR1* gene account for about 10% of all cases of Kallmann syndrome.

- Pfeiffer syndrome type 1. Five percent of cases of Pfeiffer syndrome type 1, a type of craniosynostosis, results from the substitution of a single amino acid in the *FGFR1* protein at position 252, resulting in prolonged cell signaling that leads to premature closure of the sutures in the infant’s skull, together with misshapen facial features and abnormalities of the bones in the hands and feet. Children with type 1 Pfeiffer syndrome typically have an underdeveloped midface region, widely spaced eyes (hypertelorism), an abnormally small upper jaw, and dental abnormalities.
- Osteoglophonic dysplasia. Osteoglophonic dysplasia is a rare disorder of bone growth characterized by craniofacial abnormalities and dwarfism. It results from a gain-of-function mutation in the *FGFR1* gene in which prolonged cell signaling results in premature fusion of the cranial sutures and disruption of the normal growth of the bones in the arms and legs. The term “osteoglophonic” refers to the hollow areas in the bones that show up as holes on x-ray imaging. Only about 17 cases of this disorder had been reported in the medical literature as of 2021.
- Cancers. Mutations in the *FGFR1* gene are associated with a type of cancer of the blood called 8p11 myeloproliferative syndrome, a condition in which abnormal numbers of white blood cells are produced. Most cases of the syndrome develop into acute myelogenous leukemia (AML), but some develop into lymphoma. 8p11 syndrome results from a translocation between the *FGFR1* gene on chromosome 8p and the *ZMYM2* gene on the long arm of chromosome 13 at 13q11. The exchange of material between the two chromosomes results in the *FGFR1* gene merging with the *ZMYM2* gene. This fusion leads to uncontrolled cell

growth and division, as the *FGFR1* gene's signaling function is continuously "turned on" without any stimulation by fibroblast growth factors.

The *FGFR1* gene has also been found to be abnormally active in certain types of stomach, prostate, pancreatic, ovarian, testicular, and head and neck cancer. The gene's increased activity in these cancers is associated with the rapid growth of tumors and poorer outcomes for patients diagnosed with these cancers.

FGFR2-related conditions

Craniosynostosis is the hallmark of a major group of disorders caused by mutations in the *FGFR2* gene. Craniosynostosis refers to the premature fusion of some or all of the bones of the skull due to early closure of the cranial sutures. During normal development, the bones of the skull do not completely fuse until the first to second year of life. This delayed fusion allows for passage through the narrow birth canal at delivery and for maximum brain growth during early developmental years.

Not all forms of craniosynostosis are related to mutations in the *FGFR* genes; there are more than 150 genetic disorders that involve craniosynostosis which are not related to *FGFR* mutations. The collective incidence of all forms of craniosynostosis is 1 in 2,000 to 1 in 2,500 live births.

There are seven craniosynostosis syndromes related to mutations in the *FGFR2* gene: Apert syndrome, Crouzon syndrome, Beare-Stevenson syndrome, Jackson-Weiss syndrome, most cases of Pfeiffer syndrome type 1, Pfeiffer syndrome type 2, and Pfeiffer syndrome type 3. Types 2 and 3 of Pfeiffer syndrome are considerably more severe than type 1.

Most *FGFR2*-related syndromes display some form of craniosynostosis, or distinctive facial features, and most display hand and foot deformities, Crouzon syndrome being the exception. Syndromes range from severe (neonatal death) to mild (no or only minor clinical manifestations). The characteristic facial features observed include underdevelopment of the midface, protruding eyes, down-slanting eyes, small beaked nose, protruding lower jaw (prognathism), and eyes that are unusually far apart (hypertelorism). Hand and foot anomalies are distinct for each syndrome and are sometimes used to distinguish among the disorders. One of the puzzling features of disorders caused by mutations in the *FGFR2* gene is that some specific mutations in this gene cause Crouzon syndrome in some families and Pfeiffer syndrome in others. The reason for this anomaly was not known as of 2021.

A disorder caused by mutations in the *FGFR2* gene that does not include craniosynostosis is lacrimo-auriculo-dento-digital (LADD) syndrome. LADD syndrome is a rare disorder characterized by

abnormalities of the tear duct system (lacrimo-), ears (auriculo-), teeth (dento-) and fingers (digital). It may be caused by mutations in the *FGFR3* as well as the *FGFR2* gene. Children with this syndrome typically have misshapen ears as well as hearing loss, and abnormally low saliva production as well as small teeth.

FGFR3-related conditions

Mutations in the *FGFR3* gene are associated with several types of dwarfism.

Achondroplasia was the first disease associated with FGFRs, and *FGFR3* is the only gene known to be associated with it. It is the most common form of inherited disproportionate short stature, with an incidence of 1 in 15,000 to 1 in 40,000 live births. More than 80% of cases of achondroplasia are sporadic, with a strong link to advanced paternal age. The disorder is caused by a gain-of-function mutation in the *FGFR3* gene. It is characterized by abnormal bone growth that results in short stature with disproportionately short arms and legs, a large head, and characteristic facial features that include a prominent forehead (frontal bossing) and an underdeveloped midface. Intelligence and life span are usually normal, although there is an increased risk of death in infancy from compression of the spinal cord and/or upper airway obstruction.

Hypochondroplasia is a form of short-limbed dwarfism also caused by a mutation in the *FGFR3* gene. Although it appears clinically as a mild form of dwarfism, hypochondroplasia is caused by mutations in the *FGFR3* gene that differ from those that cause achondroplasia. Children with hypochondroplasia typically have abnormally large heads (macrocephaly); broad but short hands and feet; and short, thick necks. They are at increased risk of epilepsy and intellectual disabilities.

Thanatophoric dysplasia (TD) types I and II and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN) dysplasia are the most severe forms of *FGFR*-related dwarfism. Both types of thanatophoric dysplasia are fatal with death occurring before birth or during early infancy; the term "thanatophoric" comes from two Greek words that mean "death-bearing." All reported cases of TD have been caused by *de novo* mutations of the *FGFR3* gene, as the children do not live long enough to reproduce. The most noticeable feature of thanatophoric dysplasia is a cloverleaf-shaped skull known by the German term *Kleeblattschädel*.

Only a small number of cases of SADDAN dysplasia have been reported. Although SADDAN dysplasia is much like thanatophoric dysplasia in its presentation, affected individuals survive past infancy. Patients with SADDAN dysplasia are severely affected both mentally and physically, with the most noticeable physical feature

KEY TERMS

Acanthosis nigricans—A brownish-black hyperpigmentation of the skin, most often found in the folds of the body. It can be caused by genetic disorders as well as by certain malignancies and endocrine disorders.

Acute myelogenous leukemia (AML)—A life-threatening disorder of the bone marrow in which a large number of abnormal white blood cells accumulate in the marrow and reduces the production of normal red and white blood cells and platelets. It is also called acute myeloid leukemia.

Angiogenesis—The process in which existing blood vessels give rise to new blood vessels. Angiogenesis is important in wound healing but also plays a critical role in the growth of malignant tumors.

Anosmia—Lack or loss of the sense of smell.

Congenital—Refers to a disorder which is present at birth.

Cranial suture—Any one of the seven fibrous joints between the bones of the skull.

Craniosynostosis—A condition in which one or more of the fibrous joints (sutures) in an infant's skull turns to bone prematurely. As a result, the shape of the head is affected as the infant continues to grow, and the facial features are often deformed.

Dental agenesis—Failure of the teeth to form normally during embryonic development. The complete absence of all the teeth is called anodontia.

Dwarfism—In general, a condition in which a person is considerably shorter than normal when fully grown (below an adult height of 4 feet 10 inches) as a result of an endocrine disorder, skeletal abnormality, or genetic disorder. There are about 200 different conditions that can cause dwarfism.

Fibroblast growth factors (FGFs)—A family of proteins that signal through growth factor receptors to regulate cell division, cell proliferation, and wound healing in humans and many other species.

Fibroblasts—The active cells in connective tissue, responsible for synthesizing collagen and maintaining the structural integrity of connective tissue. Fibroblasts play an important role in wound healing.

Frontal bossing—The medical term for an unusually prominent forehead, typically accompanied by a heavy brow ridge.

Gain-of-function mutation—A mutation that results in enhanced or new activity on the part of the protein encoded by the gene.

Gonadotropins—Polypeptide hormones that (in humans) include luteinizing hormone (LH) and follicular-stimulating hormone (FSH). The gonadotropins act on the sex glands (ovaries in females, testes in males) and are essential to normal sexual maturation in humans.

Growth factors—Naturally occurring proteins that stimulate cell growth, differentiation, and healing. Most growth factors function in cell signaling.

Hypertelorism—Unusually widely spaced eyes.

Macrocephaly—Having an abnormally large head.

Phosphorylation—The addition of a phosphate group to a protein molecule. Protein phosphorylation plays an important role in many biological processes, including the activation of growth factor receptors.

Polymorphism—A variation in a gene or chromosome that occurs with fairly high frequency in the general population.

Prognathism—Abnormal protrusion of either the upper or lower jaw.

Translocation—A chromosomal abnormality that results from an exchange of material between two chromosomes from different pairs (nonhomologous chromosomes). Translocation may result in the fusion of two different genes.

being the brownish-black discoloration of their skin, a condition known as acanthosis nigricans. Both SADDAN dysplasia and thanatophoric dysplasia types I and II have their own distinct *FGFR3* gene mutations.

Muenke syndrome is a rare form of craniosynostosis associated with hearing loss and a risk of learning disabilities as well as malformations of the skull and facial features. Hypertelorism is common in children with this syndrome, as are flattened cheekbones and an enlarged head (macrocephaly). Muenke syndrome is thought to

affect about 1 child in 30,000 and to account for 8% of all cases of craniosynostosis. It requires molecular genetic testing to distinguish it from other forms of craniosynostosis, however, as its clinical features are not sufficiently distinctive.

FGFR4-related conditions

Although mutations in the *FGFR4* gene had not been linked to any forms of dwarfism or craniofacial disorders as of 2021, certain polymorphisms (variations that are

One polymorphism, found in 50% of people worldwide, involves the substitution of an amino acid called arginine for glycine at position 388 in the amino acid chain of the *FGFR4* protein. Although this variation has no known effects in healthy adults, it worsens the outcome in patients with breast, head and neck, colon, and prostate cancers.

First-trimester pregnancy screening

Definition

First-trimester pregnancy screening includes blood and urine tests and ultrasound exams to determine whether the fetus is at higher risk for birth defects and whether the mother and child are at higher risk for other potentially harmful conditions. Most first-trimester tests and procedures are not diagnostic, but they might indicate the need for further screening or diagnostic testing. In some cases, screening may indicate the need for immediate intervention or treatment.

Purpose

Laboratory tests and ultrasound (high-frequency sound waves that create images of the fetus) are first-trimester pregnancy-screening procedures that do the following:

- screen for genetic disorders caused by inherited gene mutations or chromosomal abnormalities
- screen for birth defects (congenital anomalies) that may be caused by medications, chemicals, or infections
- assess the mother's general health
- screen for maternal conditions and infections that pose a risk for the mother or baby
- detect Rh incompatibility

Some first-trimester screening tests may be performed only if a woman is at a higher risk of having a baby with a genetic disorder; however, in most cases of congenital anomalies, the parents have no risk factors, and the cause of the abnormality is unknown. Most available first-trimester tests screen for chromosomal abnormalities in the fetus, especially trisomy (an extra

chromosome), which is the most common chromosomal abnormality. The risk of trisomy increases with increasing maternal age: when the mother is age 35, the risk of a chromosomal abnormality is one in 192; at age 40, it is one in 66. The most common chromosomal condition is Down syndrome, or trisomy 21—all or part of an extra chromosome 21. Screening also usually includes trisomy 13 (Patau syndrome, an extra chromosome 13), trisomy 18 (Edwards syndrome, an extra chromosome 18), and Turner syndrome, the most common monosomy (absence of a chromosome), in which a female has a damaged or missing X chromosome.

In 2021, researchers discovered a relationship between a protein called pregnancy-associated plasma protein(PAPP-A) and risk for gestational diabetes, a common complication of pregnancy. Insulin resistance associated with gestational diabetes is a health problem for pregnant women, who can pass some of the metabolic changes on to their newborns. PAPP-A has been found in the circulating blood of pregnant women and has been associated with some birth defects. The protein is thought to affect an insulin growth factor that promotes healthy tissue growth. Low levels of PAPP-A are related to higher chance of insulin resistance and gestational diabetes later in pregnancy.

Some inherited genetic disorders are more common in certain racial or ethnic groups, and first-trimester screening for these disorders is usually performed only when the mother or father belongs to one of those groups. Examples include the following:

- sickle cell disease in African Americans
- cystic fibrosis (CF) in non-Hispanic whites
- Tay-Sachs disease in people of Ashkenazi Jewish, Cajun, or French Canadian ancestry

Description

Screening for genetic disorders

First-trimester screening for genetic disorders measures certain substances in the mother's blood and images the fetus by ultrasound. The two main types are combined first-trimester screening and integrated screening.

Combined screening is the most widely used first-trimester procedure and is typically performed at 11–14 weeks of pregnancy. It includes a blood test for human chorionic gonadotropin (hCG) and PAPP-A and an ultrasound exam for possible trisomies. Detection of hCG in the blood or urine indicates pregnancy and is the basis of home-pregnancy testing.

Quantitative hCG measures the hCG level in the mother's blood and, in conjunction with progesterone levels, is used to diagnose an ectopic pregnancy that is outside of the uterus, as well as to help diagnose and monitor women at risk for miscarriage. Levels of hCG rise much more slowly with ectopic or failing pregnancies. In such cases, hCG tests may be performed over several days. Chromosomal defects, such as trisomy, tend to significantly increase hCG levels and decrease PAPP-A levels. A targeted ultrasound exam, called nuchal translucency, can detect fluid and increased space at the back of the fetus's neck, which sometimes indicates Down syndrome or another trisomy. Doctors can check hCG levels additional times early in pregnancy if there are signs that the pregnancy is not progressing as it should.

The results of hCG and PAPP-A tests and nuchal translucency ultrasound are combined to determine the risk of a chromosomal defect. This screening detects 82% to 88% of cases of Down syndrome. Combined screening is appropriate for women who want their screening results as early in pregnancy as possible. Combined screening is also appropriate for women who, in the event of a positive screening result, would choose to have a diagnostic test called chorionic villus sampling (CVS) in the first trimester and may choose to terminate an affected pregnancy.

Integrated screening for trisomies and neural tube defects involves a PAPP-A blood test and nuchal translucency ultrasound in the first trimester, followed by “quad screening” in the second trimester. Quad screening includes blood tests for alfa-fetoprotein (AFP) for neural tube defects, and hCG, estriol, and inhibin-A for trisomies. (Neural tube defects, such as spina bifida, cannot be screened for in the first trimester.) Integrated screening detects 94% to 96% of cases of Down syndrome. It is appropriate for women who want the most accurate screening test. It is also appropriate when CVS is not available and for women who would consider having

diagnostic amniocentesis in the event of a positive screen but who would not consider CVS in the first trimester because of the slightly higher risk of complications. If nuchal translucency ultrasound is not available, quad integrated screening or triple integrated screening (AFP, hCG, and estriol) detects 85% to 88% of cases of Down syndrome. Women who are already in their second trimester of pregnancy have the option of triple or quad screening but not integrated screening.

A newer screening test for chromosomal abnormalities analyzes cell-free fetal DNA in maternal blood. It can be performed as early as 10 weeks of gestation. This test is recommended for women at high risk for having a child with a chromosomal abnormality because of maternal age, family history, an ultrasound finding, or a positive blood-screening test. DNA screening can significantly reduce the need for invasive diagnostic testing by CVS or amniocentesis. It is considered much more accurate than standard screening tests, with significantly higher detection of Down syndrome and significantly fewer false positives for all three trisomies.

Carrier tests screen for genes in the mother and father that can cause genetic disorders in the child. Carrier tests can be performed before or during pregnancy. They are performed if the mother or father has a genetic disorder, a family history of a genetic disorder, or a previous child with a genetic disorder, or if he or she is a member of a racial or ethnic group at increased risk for certain genetic disorders. Because cystic fibrosis is so common, CF carrier screening is offered to all women of reproductive age.

Other screening tests

The following first-trimester pregnancy screening tests are standard for all women:

- A complete blood count (CBC) determines the numbers of different types of cells in the blood: low red blood cell counts can indicate anemia, white blood cell counts indicate the mother's ability to fight off infection, and platelet counts indicate the clotting ability of the mother's blood.
- The mother's blood type, including the presence or absence of Rh (rhesus) factor, is determined. Rh factor is a protein that is present on the surface of the red blood cells of most—but not all—people. If a mother is Rh-negative, and her fetus is Rh-positive, she may produce antibodies that attack the fetal red blood cells. This occurrence can be prevented by treating the mother with immune serum.
- Urinalysis detects red and white blood cells in the urine, which may indicate a urinary tract infection, and glucose, which may indicate diabetes. Protein levels in the urine are determined for comparison with levels later

in pregnancy, when high levels of urine protein suggest the risk of pre-eclampsia, a life-threatening condition in the mother.

- Urine cultures are used to screen for urinary tract infections.
- A glucose-screening test is performed on women with risk factors for diabetes or those who had gestational diabetes mellitus during a previous pregnancy.
- Maternal blood is screened for antibodies to rubella (German measles), which indicate past infection or vaccination against the disease. Rubella in early pregnancy can cause birth defects. Since women without the antibodies cannot be vaccinated until after giving birth, they must avoid anyone who is infected with this highly contagious virus.
- Hepatitis B and C infections can be passed to the fetus. All pregnant women are screened for hepatitis B, and those with risk factors are screened for hepatitis C.
- All pregnant women are screened for syphilis and chlamydia, because those infections can cause complications in the mother and infant. Infected women are treated during pregnancy and then retested.
- Women are screened for gonorrhea if they have risk factors for infection, such as being under age 25 or living in an area with high gonorrhea rates.
- All women are screened for HIV, which causes AIDS. HIV can be transmitted to the baby before or during birth, but medications and other steps greatly reduce the risk of transmission.
- Women are screened for tuberculosis (TB) if they are at high risk for the disease, live in close contact with someone with TB, or are infected with HIV.

Precautions

First-trimester pregnancy-screening tests pose no risk to the mother or fetus. Screening tests for birth defects, however, are not diagnostic—they merely indicate whether the fetus is at normal or increased risk for a birth defect. Screening test results depend on both the nuchal translucency technique and on an accurate determination of gestational age. If the gestational age is wrong, the test results may not be accurate.

Furthermore, screening cannot detect all fetal abnormalities. A positive screening test result is generally followed by a diagnostic test. Women may choose to substitute diagnostic tests for screening tests, especially if the parents have a family history of birth defects or a previous child with birth defects, or if they belong to certain ethnic groups. The American College of Obstetricians and Gynecologists recommends that diagnostic tests—CVS in the first trimester or amniocentesis in the

KEY TERMS

Amniocentesis—A procedure performed between 16 and 18 weeks of pregnancy, in which a needle is inserted through a woman's abdomen into the uterus to draw out a small sample of the amniotic fluid from around the fetus; either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about various genetic disorders and other medical conditions in the fetus.

Carrier testing—Testing performed to determine whether someone possesses one changed copy and one unchanged copy of a particular gene.

Chorionic villus sampling (CVS)—A procedure involving removal of a small placenta sample during pregnancy to obtain fetal chromosome results.

Combined first-trimester screening—Blood tests for pregnancy-associated plasma protein A and human chorionic gonadotropin and an ultrasound exam for chromosomal abnormalities.

Complete blood count (CBC)—A measurement of blood levels of red blood cells, white blood cells, and platelets.

Cystic fibrosis (CF)—A respiratory disease characterized by chronic lung disease, pancreatic insufficiency, and an average age of survival of 20 years. Cystic fibrosis is caused by mutations in a gene on chromosome 7 that encodes a transmembrane receptor.

Down syndrome—A chromosomal disorder caused by the presence of all or part of an extra 21st chromosome.

Edwards syndrome—Trisomy 18; a genetic disorder caused by an extra chromosome 18 that can be screened for in the first trimester.

Gestational diabetes—This type of diabetes (a condition that negatively affects how the body uses carbohydrates) occurs in pregnant women who did not have diabetes before becoming pregnant. It can lead to health problems and pregnancy and birth complications.

Human chorionic gonadotropin (hCG)—A protein produced in early pregnancy; fetal chromosomal abnormalities can significantly increase hCG levels in maternal blood.

Integrated screening—Blood tests and ultrasound in the first trimester, followed by blood tests for three or four proteins in the second trimester, to screen for chromosomal abnormalities and neural tube defects.

Nuchal translucency ultrasound—Specialized ultrasound imaging that looks for a larger-than-normal space and fluid at the back of the first-trimester fetal neck to screen for chromosomal abnormalities.

Patau syndrome—Trisomy 13; an extra chromosome 13.

Pregnancy-associated plasma protein A (PAPP-A)—An early pregnancy protein in maternal blood and urine; fetal chromosomal abnormalities can cause decreased PAPP-A levels.

Rh factor—Rhesus factor; a protein on the surfaces of red blood cells of many people; if a fetus is Rh-positive, and the mother is Rh-negative, the mother must be treated with immune globulin to prevent the production of antibodies that could cross the placenta and attack the fetal blood cells.

second trimester—and/or targeted ultrasound be offered to all women in place of screening tests, regardless of risk factors. However, CVS and amniocentesis are invasive procedures that carry a very small risk of miscarriage or other complications.

If a woman is pregnant with multiple fetuses, blood tests for Down and Edwards syndromes are less reliable. That is because the levels of PAPP-A and free beta hCG increase, and the proteins from an affected fetus may be more difficult to detect in the mother's blood. However, nuchal translucency ultrasound assesses each fetus independently.

Preparation

Screening for birth-defect risk is a personal choice. Many women want as much information as possible about

their baby's health and want to ease any anxieties. Detection of a birth defect in the first trimester provides time to consider options. These may include terminating the pregnancy or preparing to care for a child with a birth defect and arranging for specialized medical care during and after the child's birth. Other women would not consider terminating an affected pregnancy and would rather not know about any problems beforehand.

Some women decide against screening tests because they know they would not choose to have an invasive diagnostic test if the screening test were to indicate a higher risk of an abnormality. Other women choose to forego the uncertainty of a screening test and have a diagnostic test instead. Pregnant women and their families may find it useful to consult a genetic counselor before deciding to have first-trimester screening for birth defects.

QUESTIONS TO ASK YOUR DOCTOR

- What type of first-trimester pregnancy screening do you recommend?
- What information is obtained from first-trimester screening?
- What does it mean if my screening results are negative?
- What are my options if the screening results are positive?
- What are the advantages and disadvantages of having diagnostic testing instead of screening?

A woman's risk factors are assessed in preparation for first-trimester screening. A questionnaire may ask about personal and family histories of birth defects, ethnicity, maternal age of 35 or older, and pre-existing diabetes.

Aftercare

Some screening tests may be performed or repeated later in the pregnancy. The CBC is repeated later. An Rh-negative mother with an Rh-positive baby will be tested later for Rh antibodies to determine whether she requires immunoglobulin. Glucose screening for gestational diabetes and screening for group B streptococcus infection are also performed later in pregnancy. As of 2021, researchers were studying whether PAPP-A and glucose levels at various points during pregnancy might better tell how gestational diabetes develops.

Results

Results of first-trimester pregnancy screening are available in about one week. The health care provider and possibly a genetic counselor will explain the results and offer options for any follow-up, such as diagnostic tests. Results of combined screening are generally provided as a risk number: If the risk is higher than a predetermined cut-off value, such as one in 300 or higher, the result is considered positive, with the baby at risk for a chromosomal abnormality. Women with higher-than-normal risk values are offered CVS in the first trimester, amniocentesis in the second trimester, or, rarely, fetal blood testing. However, CVS or amniocentesis is generally offered to all women, regardless of screening results. A genetic counselor can help women assess the benefits and risks of diagnostic testing. Counseling also may be helpful for addressing issues raised by pregnancy termination or caring for a child with a genetic disorder.

Combined first-trimester screening identifies about 85% of fetuses with Down syndrome and up to 75% of those with Edwards syndrome. About 5% of results are false positives. Certain other screening systems are somewhat different. With contingent sequential screening for Down syndrome, trisomy 18, and neural tube defects, the following is true: If the first-trimester combined screening result is negative, no further testing may be offered; if the result is positive, a diagnostic test is offered; if the result is intermediate, a second-trimester screening test is offered. This system diagnoses 88% to 94% of cases of Down syndrome. With stepwise sequential screening for Down syndrome, trisomy 18, and neural tube defects, the following is true: If first-trimester screening is negative, a second-trimester screening test is offered; if the first-trimester screen is positive, a diagnostic test is offered. This system diagnoses 95% of cases of Down syndrome.

Fluorescence in situ hybridization

Definition

Fluorescence in situ hybridization (FISH) is a powerful technique used to identify the presence of specific chromosomes or parts of chromosomes through the attachment (hybridization) of fluorescent DNA probes to available chromosomal DNA. The fluorescent DNA sequence used to attach to the cellular DNA is called the probe and is created in the experimental laboratory. Sometimes an RNA sequence is used as the probe instead of DNA. Examining the labeled cellular DNA under special lighting reveals the presence or absence of a fluorescent signal that indicates specific genes. FISH can be used on tissue preparations, on blood or bone marrow smears, directly on cells, or on nuclear isolates.

Description

In situ is Latin for “in the original place,” which, in the case of FISH, means inside a human cell or tissue. To hybridize with something means to attach to it in a very selective, specific manner. In situ hybridization (ISH) is the attachment of a very specifically designed DNA probe to cellular DNA (the original place). FISH uses a DNA probe that can be labeled with a fluorescent compound and emits colored light when it is exposed to specific light wavelengths under a microscope. FISH can detect specific DNA or RNA sequences that are present in a human cell by taking advantage of DNA’s double-stranded nature.

FISH and DNA structure

In a normal human cell, DNA is compartmentalized in an area known as the cell’s nucleus. Within this nucleus, the preferred conformation of DNA is two strands wrapped around each other and twisted. This twisted structure is known as the DNA helix. DNA is made up of chemical bases that are represented by the letters C, T, G, and A. This is the DNA alphabet that makes up each strand of DNA. The letters of each strand pair up in a specific manner when twisting to form the helix. All the T bases pair with A bases, and all the G bases pair with C bases. Different combinations of these bases are put together in three-letter “words” called codons. The arrangement of the words is what determines what a gene will encode for, gives the gene its meaning, and therefore tells the body how to grow and develop. DNA is transcribed into RNA, the beginning of expression of DNA in a cell. To express the product that the gene is encoding, RNA is translated into proteins that function in many capacities for life.

FISH takes advantage of the tendency of DNA to form base pairs with its corresponding letters. The DNA inside a cell can be experimentally exposed and temporarily unraveled from its helical structure. To denature DNA means to take the unraveling a step farther and undo the bonds between the bases from the two strands. Once the single-stranded bases are exposed, carefully designed DNA sequences that can be fluorescently labeled can be used to probe the cell’s set of DNA or RNA. At specific temperatures and under standardized laboratory conditions, the probe is able to hybridize with (pair up with) and therefore label the cellular DNA. This technique can be used to search for specific gene sequences in human tissue that would cause clinical complications. FISH can also reveal the actual location of a DNA sequence on a chromosome.

The FISH technique

The general procedure for FISH involves fixing samples of chromosomes or human tissue onto a piece of glass known as a slide (it slides into place on the viewing platform of a microscope when the sample is ready to examine). To prepare the tissue on the slide for hybridization, it is treated with chemicals to permeabilize (open up) the cells and expose the DNA. The chemicals also denature the DNA so that it is single-stranded and ready for the probe. A specific chemical hybridization solution containing the probe is applied to the slide so that the probe can hybridize with cellular DNA. This hybridization solution controls the degree of specificity to which the probe hybridizes to the target sequence. Factors such as the temperature, pH, and salt concentration can be changed to control the specificity of the hybridization. When the probe is made of RNA or is being

KEY TERMS

Aneuploidy—Having too many or too few copies of a specific chromosome; the most common forms are trisomy (three) and monosomy (one); two copies of a chromosome is normal.

Chromosome—A thread-like structure of DNA and associated proteins called chromatin that carries multiple genes.

DNA—Deoxyribonucleic acid, inheritable material that constitutes the building blocks of life.

Fluorochrome—A fluorescent compound used for visualization in FISH.

Gene—A sequence of chromosomal DNA that functions as a hereditary unit and encodes for the production of a functional product.

Locus (plural: loci)—Position occupied by a gene on a chromosome.

Nuclear isolate—An isolated preparation of the contents of the nucleus of a cell, which contains the DNA.

RNA—Ribonucleic acid, the intermediate step between DNA and its final expression product. DNA is transcribed into RNA and RNA is translated into protein.

Transcription—The process by which DNA is changed into RNA.

Translation—The process by which RNA is changed into protein.

hybridized to RNA, special precautions must be taken because single-stranded RNA is less stable than DNA and easily degraded. Any excess probe is washed away.

Probes can be labeled directly with an attached fluorescent molecule; or indirectly, when a specific fluorescent-labeled antibody or labeled binding protein is used to detect a tag attached to the probe sequence. Using the indirect method, the probe itself only contains an attachment point for the fluorescent antibody or binding protein. With this method, the probe by itself is not fluorescent. Once the fluorescent binding molecules are applied, the slide can be viewed on a special microscope designed for fluorescence. The microscope applies a beam of light, set at a specific light wavelength, to the DNA on the slide. The fluorescent tags on the DNA emit colored light in response to specific wavelengths. The fluorescent molecules do not fluoresce under sunlight.

Fluorescent labeling

Fluorescent compounds are known as fluorochromes. An example of a fluorochrome that may be used is fluorescein isothiocyanate (FITC). FITC can be attached, or conjugated, to an antibody for the tag on the DNA probe. FITC can fluoresce only under specific narrow wavelengths of light and does not fluoresce in sunlight. Sunlight contains many wavelengths of light measured in nanometers (nm). Short wavelengths less than 400 nm are types of ultraviolet light that have very high energy. The visible spectrum of light ranges from 400–780 nm. The infrared long wavelengths of light lie between 780 nm–1 mm. FITC compounds are designed to fluoresce only when specific narrow ranges of wavelengths are shining on them. The wavelength required varies from compound to compound. A dark room and a special microscope equipped with such lighting are used for this purpose. Fluorescent labeling can allow two or more different probes to be visualized at the same time because they fluoresce with different colors and can be distinctly visualized. Special filters have been developed to allow simultaneous visualization of several fluorescent molecules at once. When many gene loci (locations) on a chromosome are being labeled, the process is referred to as a chromosome paint. Fluorescent dyes are subject to photobleaching (fading) and so are not permanent preparations. Digital imaging systems can store the fluorescent images permanently and make quantitative measurements.

Once the DNA has been visualized, many types of information can be revealed. FISH is an extremely powerful technique used for many applications in medical research and diagnosis. FISH can be used to determine chromosome structure, chromosome deletions, and chromosomal gene mapping; to detect the expression of genes when probing RNA; to localize viral DNA sequences; to diagnose viral diseases based on the presence of viral DNA sequences; and to localize genes involved in cancer formation, forensics, and sex determination.

FISH applications in medicine

There are specific types of genetic disorders whose detection and diagnosis have been revolutionized by the FISH technique in accuracy, time, and cost. FISH findings have been determined as so important, that the standing committee for the International System on Cytogenetic Nomenclature (ISCN) established a specific genetic nomenclature just to describe FISH findings. Deletion syndromes, such as Prader-Willi syndrome, were first characterized by high-resolution analysis of chromosomes. Because the deletions in some of these disorders are small and difficult to detect, they are referred to as

microdeletion syndromes. The FISH technique has revolutionized the detection and diagnosis of microdeletion syndromes. In some cases, the prevalence of these diseases had not been realized before FISH.

FISH has had a great impact on the characterization of chromosome structural abnormalities that are difficult to diagnose. Given a patient with a genetic disease that has multiple possible gene mutations, FISH, with multiple fluorochromes, can be used to determine the precise nature of the chromosomal rearrangements. FISH can be used to literally map out the exact chromosomal structure in DNA samples from such patients to a level of accuracy previously unknown. This kind of diagnosis would not have been confirmed prior to the advent of FISH. FISH studies can also be used to screen for fetal aneuploidies (too many or too few of one type of chromosome), such as Down syndrome.

FISH is used in cancer analysis. Exploration of the acquired chromosomal abnormalities found in cancer cells is an important area of research. Techniques other than FISH usually require growing sample cells in laboratories for study, a task that can prove very difficult. Because FISH can be used on nondividing cells, it can greatly augment standard research techniques. FISH studies are also being used to look for early relapse and residual disease in cancer patient bone marrow transplants from opposite sex donors. The success of transplant engraftments is monitored by dual fluorochrome FISH studies that can label and differentiate between the proportions of female XX and male XY cells in bone marrow and blood.

FISH is used in gene mapping of specific chromosomes and chromosomal regions. The DNA sequences within a chromosome can be determined by labeling FISH probes with multiple different fluorochromes and distinguishing their hybridization color patterns. Chromosomes are composed of DNA and associated proteins. The combination of DNA and protein found in chromosomes is called chromatin. In a new technique called fiber FISH, chromosome-specific chromatin fibers are stretched out on a glass slide and hybridized with gene locus-specific probes. Fiber FISH achieves higher levels of fine-resolution mapping of DNA sequences than normal FISH.

FISH is a powerful technique. Because of its high accuracy, time efficiency, and relatively low cost, it is quickly becoming the preferred method by which to accomplish many clinical and research applications.

Focal dermal hypoplasia

Definition

Focal dermal hypoplasia, previously known as Goltz syndrome, is a rare genetic skin condition. It is a dominant X-linked trait that primarily affects females because it is usually lethal in males before birth.

Description

Focal dermal hypoplasia (FDH) was first described by R. W. Goltz in 1962. It is a genetic disorder that affects the appearance and function of the skin, causing characteristic localized (focal) patches of thin or absent (hypoplasia) skin (dermal). FDH is a member of a larger family of genetic disorders known as the ectodermal dysplasias, which include abnormalities of the skin, hair, teeth, nails, and/or the sweat glands. In FDH, the skin abnormalities include areas where the skin is completely absent or thin (lesions), discolored, itchy, or blistered. Hair may be missing in patches, and the teeth are usually poorly formed. Nails also may be unusual in appearance. In addition to these characteristics, individuals with FDH can have skeletal malformations and eye problems.

The obvious symptoms of FDH are the result of improper functioning of the skin, an organ whose

Coloboma—A birth defect in which part of the eye does not form completely and appears to be cleft or notched.

De novo mutations—A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

Dermis—The layer of skin beneath the epidermis.

Ectodermal dysplasia—A hereditary condition that results in the malformation of the skin, teeth, and hair. It is often associated with malfunctioning or absent sweat glands and/or tear ducts.

Epidermis—The outermost layer of the skin.

Goltz syndrome—Focal dermal hypoplasia (FDH).

Hyperhidrosis—Excessive perspiration that may be either general or localized to a specific area.

Hypohidrosis—Insufficient perspiration or absent perspiration that may be either general or localized to a specific area.

Hypoplasia—Incomplete or underdevelopment of a tissue or organ.

Papilloma—Any benign localized growth of the skin or the linings of the respiratory and digestive tracts. The most common papillomas are warts.

X-linked dominant—A gene or trait located on an X chromosome that is expressed in preference to the same gene on the other X chromosome; X-linked mutations are often lethal in males because males have only one X chromosome.

multiple functions are often overlooked. The skin consists of two layers: the outer skin (epidermis) and the inner skin (dermis). The epidermis layer protects the body from environmental threats such as temperature variations, bacterial infections, and toxic chemicals. The dermis contains cells that manufacture the protein collagen. Collagen makes up about one-fourth of all the protein in the human body and plays a vital role in wound healing, skin and muscle support, and bone formation. With FDH, type IV collagen in the dermis is abnormally formed and may be present as loose collagen bundles and fibers with loss of regular bands. The epidermis is deformed or completely absent. The importance of collagen in many of the body's tissues explains the varied

symptoms of FDH, which are observed in parts of the body as different as the bones, skin, hair, and fingernails.

Genetic profile

FDH is caused by mutations in the *PORCN* gene on the short arm (p) of the X chromosome at position 22.3 (Xp22.3). It is inherited as an X-linked dominant trait with close to 100% fetal mortality in males, since males have only one X chromosome. The gene mutations may be inherited from a parent, but they most often occur as a sporadic or *de novo* mutation in the egg or sperm cell, fertilized egg, or early embryo, so the parents are unaffected. Males who do survive generally have milder symptoms because they have a *de novo* mutation that occurred later in development, so the mutated gene is present in only some of their cells. The *PORCN* gene produces a protein that modifies Wnt proteins, which are important components of the signaling pathways that regulate fetal development of the skin, bones, and other structures. *PORCN* gene mutations prevent the production of functional *PORCN* protein. Without *PORCN*, the unmodified Wnt proteins appear to be unable to move out of cells to participate in signaling during early development.

Demographics

FDH is presumed to be rare, but its prevalence is not known. It occurs with equal frequency in all races and across all geographic regions. Because it is an X-linked dominant condition, about 90% of surviving patients are female.

Signs and symptoms

FDH is characterized by localized areas of malformed skin (skin lesions) that appear underdeveloped, streaked, or absent. The skin may lack color (pigmentation) in the affected areas or may be streaked with lines (linear pigmentation). The affected areas may look and feel inflamed or irritated, with itching, blistering, reddening, swelling, and even crusting and bleeding. Fatty deposits (papillomas) are usually present in sensitive skin areas, such as the gums, lips, tongue, armpits, vaginal opening, and anus. Nodules of yellowish fatty tissue can grow on the affected skin, particularly in skin folds.

People with FDH often have excessive skin growth on the palms of the hands and on the soles of the feet. Because of this overgrowth of skin layers, increased sweating (hyperhidrosis) often occurs in these areas. Similarly, because of an undergrowth of skin in other parts of the body, many affected people do not sweat normally (hypohidrosis) throughout the rest of their body.

QUESTIONS TO ASK YOUR DOCTOR

- Can you explain the genetic basis of focal dermal hypoplasia?
- Did my daughter inherit focal dermal hypoplasia?
- What are the primary symptoms associated with focal dermal hypoplasia?
- What is my child's prognosis?
- Can you recommend an organization or other resources for additional information about focal dermal hypoplasia?

Additionally, people with FDH may have patches of hair loss on the scalp and pubic region. The teeth are often malformed, mispositioned, or absent, and cavities are commonplace because of missing or incomplete tooth enamel.

Unusual bone formations are also associated with FDH. Missing or extra fingers or toes, webbed fingers or toes, permanently bent fingers or toes, and fusion of bones in the fingers or toes have all been observed. Other skeletal abnormalities, such as curvature of the spine, underdevelopment or protrusion of the lower jaw, and fused vertebrae, may be present.

Individuals with FDH are likely to exhibit facial asymmetry, underdeveloped ears, wide-set eyes, and a pointed chin. Hearing loss, either at birth or developing later, is common, due to underdevelopment of the ears. Many eye abnormalities have been observed with FDH. These range from missing eyes (anophthalmia) and incomplete formation of the eye (coloboma) to clouding of the cornea, drooping eyelids, and crossed eyes. The mucous membranes of the nose and throat may also be affected. Intellectual disability occurs in some cases.

Diagnosis

FDH is generally diagnosed by characteristic skin abnormalities coupled with the characteristic fatty deposits in the gums, lips, armpits, vagina, and/or anus. It is distinguished from the other possible ectodermal dysplasias by lack of pigmentation of the skin in some of the affected areas, abnormal sweating, lack of cysts in the eyes, and the presence of tear ducts. The papillomas in the genital areas are often misdiagnosed as genital warts, but FDH patients will test negative for human papillomavirus (HPV), which causes common genital warts.

Genetic testing for FDH, including prenatal diagnosis, is possible as of 2021.

Treatment and management

Treatment and management of FDH varies depending on the symptoms. Dermatological treatments, such as skin creams, as well as more targeted treatments, are usually indicated. Some affected individuals require dental work or surgery. Others require respiratory therapy to keep the nose and throat clear. Certain skeletal deformations may be corrected with orthopedic surgery. Because of the associated abnormal sweating patterns, affected individuals must avoid heat and strenuous exercise.

Prognosis

FDH is usually lethal in male fetuses. With medical treatment, females with FDH can expect a normal lifespan.

Fragile X syndrome

Definition

Fragile X syndrome is the most common form of inherited developmental disability. Individuals with this condition have developmental delay, variable levels of intellectual disability, and behavioral and emotional difficulties. They may also have characteristic physical traits. In general, males have moderate intellectual disability, and females have mild intellectual disability.

Description

Fragile X syndrome with intellectual disability is a neurodevelopmental disorder. It is also known as Martin-Bell syndrome, Marker X syndrome, and FRAXA syndrome. Fragile X tremor/ataxia syndrome (FXTAS) is classified as a neurodegenerative disorder. Both syndromes are caused by mutations in the *FMR1* gene located on the X chromosome. *FMR1* produces the fragile X mental retardation protein (FMRP). This protein binds to RNA and is presumed to be involved in the translation of messenger RNA (mRNA) during protein synthesis and to play an important role in brain development.

Genetic profile

Each cell in the body contains 23 pairs of chromosomes, one member of each pair inherited from each parent. These chromosomes consist of genetic material (DNA) needed for the production of proteins for growth, development, physical/intellectual characteristics, and metabolism. The first 22 pairs of chromosomes are the same in males and females. The remaining two chromosomes are called the sex chromosomes (X and Y). The sex chromosomes determine whether a person is male or

female. Males have only one X chromosome, which is inherited from the mother at conception, and they receive a Y chromosome from the father. Females inherit two X chromosomes, one from each parent.

Fragile X syndrome is caused by a mutation in a gene called *FMR1*, which is located on the X chromosome. The fragile X mutation involves a short sequence of DNA in the *FMR1* gene. This sequence is designated CGG. Normally, the CGG trinucleotide sequence is repeated between six and 54 times. People who have repeats in this range do not have fragile X syndrome and are not at increased risk to have children with fragile X syndrome. Those who are affected by fragile X syndrome with intellectual disability have expanded CGG repeats of more than 200 in the first exon (protein-coding region) of the *FMR1* gene (the full mutation). CGG repeats of 55–200 cause premutations and FXTAS.

People who carry a premutation do not usually have developmental delays or behavioral symptoms; however, they are at risk for having children with FXTAS or fragile X syndrome with intellectual disability, because the size

of the premutation can expand over succeeding generations. Since the *FMR1* gene is located on the X chromosome, males are more likely to develop symptoms than females, because males have only one copy of the X chromosome. Males who inherit the full mutation are expected to have mental impairment. A female's normal X chromosome may compensate for her chromosome with the fragile X gene mutation. Females who inherit one full mutation have an approximately 50% risk of mental impairment. The phenomenon of expanding trinucleotide repeats in successive generations is called anticipation. More than 99% of cases of fragile X syndrome are caused by CGG repeat expansions; fewer than 1% of cases are caused by point mutations or deletions in the *FMR1* gene.

Fragile X syndrome is inherited in an X-linked dominant manner. When a man carries a premutation on his X chromosome, it tends to be stable and usually will not expand if he passes it on to his daughters. (He passes his Y chromosome to his sons.) Thus, all of his daughters will be premutation carriers. When a daughter who carries a premutation has children, the premutation becomes

unstable and can expand as she passes it on. Therefore, a man's grandchildren are at greater risk of developing the syndrome. There is a 50% risk of a premutation carrier female transmitting the mutation with each pregnancy. The likelihood of the premutation expanding is related to the number of repeats present; the higher the number of repeats, the greater the chance that the premutation will expand to a full mutation in the next generation.

All mothers of children with a full mutation are carriers of an *FMR1* gene expansion. Another aspect of fragile X syndrome is mosaicism in 15% to 20% of those affected by the condition. Mosaicism means that only some of the cells in the body have the fragile X mutation. This is caused by a trinucleotide repeat expansion or premutation expansion occurring in a cell of the early embryo or developing fetus. Only cells that come from the cell with the mutation are affected.

Researchers continue to study the possible causes of fragile X syndrome. In 2020, researchers at Tokyo University found that specific groups of molecules might contribute to the abnormal development of neural stem

cells in fetal brains. Learning more about molecular pathways that contribute to fragile X syndrome will help with assessing risk in individuals.

Demographics

Fragile X syndrome affects males and females of all ethnic groups. It is estimated that there are about one in 7,000 males affected with fragile X syndrome. There are approximately half as many females with fragile X syndrome as males (one in 11,000); however, the carrier frequency in unaffected females is one in 100 to one in 600. The average age of children at diagnosis of fragile X syndrome is 35 to 42 months.

Signs and symptoms

Individuals with fragile X syndrome appear normal at birth, but their development is delayed. Most boys with fragile X syndrome have mental impairment. The severity of mental impairment ranges from learning disabilities to severe intellectual disability. Behavioral problems include attention deficit and hyperactivity at a young age. Some may show aggressive behavior in adulthood. Short attention span, poor eye contact, delayed and disordered speech and language, emotional instability, and unusual hand mannerisms (hand flapping or hand biting) are also seen

frequently, as are behavioral characteristics such as whirling and spinning. These symptoms are noticeably similar to symptoms of autism spectrum disorder.

Characteristic physical traits appear later in childhood. These traits include a long and narrow face, prominent jaw, large ears, and enlarged testes. In females who carry a full mutation, the physical and behavioral features and intellectual disability tend to be less severe. About 50% of females who have a full mutation are intellectually disabled. Females may develop premature ovarian insufficiency (POI) or premature ovarian failure, in which the ovaries cease functioning before age 40, with irregular menstrual periods and menopausal symptoms.

Children with fragile X syndrome may have frequent ear and sinus infections. Near-sightedness and lazy eye are also common. Many babies with fragile X syndrome have trouble with sucking, and some experience digestive disorders that cause frequent gagging and vomiting. A small percentage of children with fragile X syndrome have seizures. Children with fragile X syndrome tend to have loose joints that may result in joint dislocations. Some children develop a curvature in the spine, flat feet, and a heart condition known as mitral valve prolapse.

Diagnosis

A child with signs of speech, language, or motor developmental delays of unknown cause might be tested for fragile X gene mutations, especially if there is a family history of the condition. Definitive identification of fragile X syndrome is made by genetic testing to assess the number of CGG sequence repeats in the *FMR1* gene. Genetic testing for the fragile X mutation can be performed on the developing fetus before birth through amniocentesis or chorionic villus sampling (CVS); this test detects 99% of trinucleotide repeat expansions in the *FMR1* gene. Prenatal testing will only be performed after the fragile X carrier status of the parents has been confirmed and the couple has undergone genetic counseling.

A spring 2021 study from the University of Wisconsin-Madison reported that use of artificial intelligence (AI) leads to an earlier diagnosis of fragile X syndrome. The researchers input information from medical records of 1.7 million patients and matched several other diagnoses that are common among those who have the genetic condition, such as certain heart conditions. Through machine learning, the AI diagnosis can occur five years earlier on average, alerting doctors to risk sooner. The AI diagnosis still was being studied in 2021.

Treatment and management

There is no cure for fragile X syndrome. Management includes speech therapy, occupational therapy, physical

QUESTIONS TO ASK YOUR DOCTOR

therapy, and special education. Mainstreaming children with fragile X syndrome into regular classrooms is encouraged because they do well imitating the behavior of others. Drugs may be used as needed to treat hyperactivity, seizures, and other problems. Establishing a regular routine, avoiding overstimulation, and using calming techniques may also help in the management of behavioral problems. Children with a defective heart valve should see a heart specialist and take medications before surgery or dental procedures. Children with frequent ear and sinus infections may need medications or have special tubes placed in their ears to drain excess fluid.

Prognosis

Early diagnosis and intensive intervention offer the best prognosis for individuals with fragile X syndrome. Adults with fragile X syndrome may benefit from vocational training and may need to live in a supervised setting. Lifespan is typically normal.

Fraser syndrome

Definition

Fraser syndrome is a rare autosomal recessive genetic disorder that primarily affects the eyes, genitalia, and urinary tract.

Other names for Fraser syndrome include:

- Cryptophthalmos syndactyly syndrome
- Cryptophthalmos syndrome
- Cryptophthalmos with other malformations
- Fraser-Francois syndrome
- Meyer-Schwickerath syndrome
- Ullrich-Feichtiger syndrome

Description

Fraser syndrome is named for Canadian geneticist C. R. Fraser, who first described the syndrome in 1962. Individuals affected with Fraser syndrome appear to have

hidden eyes because the skin of their eyelids is partially or fully sealed shut. This condition is called cryptophthalmos and is classified into three types: complete, in which the eyelid is completely fused over an existing eye; incomplete, in which the eyelid is only partially fused over the underlying eye; and abortive, in which the eyelid is completely fused and the underlying eye does not form.

Approximately half of all individuals affected with Fraser syndrome have abnormalities of the genitals, while 37% have renal (kidney) problems, including the absence of one or both kidneys. Some individuals also have abnormalities of the larynx or voice box, of the middle and outer ear, and of the fingers and toes.

Genetic profile

Fraser syndrome is caused by mutations in the *FRAS1*, *FREM2*, or *GRIP1* genes. Nearly half of all cases of Fraser syndrome are caused by mutations in the *FRAS1* gene. *FREM2* and *GRIP1* gene mutations are responsible for a small percentage of cases.

FRAS1 and *FREM2* genes produce FRAS1 and FREM2 proteins and are part of a group of proteins called the FRAS/FREM complex. These proteins are responsible for helping produce the FRAS and FREM complex, which are thin sheets of tissue, called basement membranes that support cells in many tissues in the body. These complexes are extremely important during fetal development, particularly in connecting the top layer of the skin to the tissues beneath. They are also important in the proper development of other organs and tissues, such as the kidneys.

Mutations in the *FRAS1* and *FREM2* genes prevent formation of the FRAS/FREM complex and cause the FRAS/FREM complex to be missing in basement membranes of the skin. When this occurs, the top layer of skin is detached, causing blisters to form during development. These blisters are likely responsible for the abnormalities of the eyes, fingers, and toes seen in Fraser syndrome. Scientists have not yet discovered how the lack of the FRAS/FREM complex may cause the kidney and genital abnormalities seen in Fraser syndrome.

The genetic mutations that cause Fraser syndrome are inherited in an autosomal recessive pattern, which means both copies of the gene in each cell have mutations. The parents of an individual with an autosomal recessive condition each have one copy of the mutated gene, making them carriers. Carriers generally do not show signs and symptoms of the condition, but if two carriers have children, they have a 25% chance of passing on the condition with symptoms to their child.

Demographics

Fraser syndrome is very rare, occurring in less than 1 of every 100,000 births. It has been reported that the frequency of the syndrome is over 100 times higher in the Roma (gypsy) population as in the non-Roma population.

As in all recessive genetic disorders, both parents must carry the gene mutation in order for their child to have the disorder. Approximately 15% of individuals diagnosed with Fraser syndrome have been observed in cases where the parents are related by blood. Parents with one child affected by Fraser syndrome have a 25% likelihood that their next child will also be affected with the disease.

Signs and symptoms

Fraser syndrome is characterized by hidden eyes resulting from either partial or complete fusion of the eyelids. This condition may be observed on only one side (unilaterally), but it is generally observed in both eyes of affected individuals (bilaterally). In most cases the underlying eyes are not fully formed, which causes small eyes called microphthalmia. In some cases of Fraser syndrome the underlying eyes are completely absent.

Individuals with Fraser syndrome have abnormal or absent tear ducts and widely spaced eyes, a condition called hypertelorism. Blindness from birth is quite common in affected individuals. However, in cases where there is a functioning visual pathway to the retina, the inner light-sensitive layer of the eye, partial vision has been observed.

Approximately half of those individuals affected with Fraser syndrome have syndactyly, a partial or complete fusion of the fingers or toes. In cases of Fraser syndrome, the observed syndactyly is most often of the third and fourth digits of the hands or feet. An extra finger or toe situated outside the normal fifth digit, called postaxial polydactyly, and webbing of the fingers or toes are also symptoms seen in individuals with Fraser syndrome. The only other bone abnormality seen with any high frequency is a greater than normal width of the cartilaginous joint between the pubic bones in the front of the pelvis.

Abnormalities of the middle and/or outer ear occur in approximately 50% of affected individuals. These symptoms range from malformations and closures of the outer structures of the ear, called the pinna or the auricle, to an absence of the auditory canal (Eustachian tube). In cases where the Eustachian tube is absent, connective tissue fills the space where the auditory canal should be and bone covers what would be the opening of the auditory canal to the outer ear. As a result of these abnormalities, some individuals may be deaf or have hearing problems.

KEY TERMS

Autosomal recessive—Genetic transmission of a trait or condition in which two copies of a gene must be present.

Cerebrospinal fluid—The fluid that surrounds the brain and spinal cord.

Cryptophthalmos—Condition in which the eyelid does not form correctly.

Diaphragm—Dome-shaped muscle and fiber that separates the torso into two sections, thoracic and abdominal.

Eustachian tube—Small tube that connects the middle ear to the throat.

Hypospadias—Congenital anomaly in which the opening of the penis is located underneath the penis rather than at the tip.

Mesentery—Tissue that attaches the intestines to the abdominal wall.

Microphthalmia—Abnormally small eyes.

Scrotum—The sac of skin that holds the testicles.

Syndactyly—Fusion of fingers or toes.

Urethral atresia—Abnormal closure of the tube that leads from the bladder to the outside of the body.

Approximately 85% of those affected with Fraser syndrome have abnormalities of the nose. The most common nasal abnormalities are blockage or narrowing of the nasal cavities that open into the mouth and throat by excess bone or by membranous tissue. Forking of the tongue and cleavage of the internal nasal passage are also seen.

Blockage and narrowing of the larynx is commonly associated with Fraser syndrome. Occasionally an abnormal web-like structure is seen in the vocal apparatus that causes an inability of speech if not corrected.

Abnormalities of the digestive system, otherwise known as the gastrointestinal or GI tract, are also common. These abnormalities include an incomplete development of the mesentery, or membrane that connects the small intestine to the back wall of the abdominal cavity; malrotation of the small intestine; umbilical hernia, a protrusion of parts of the large intestine through an abnormal opening in the abdominal wall near the navel; and defects of the diaphragm, the large muscle that separates the upper and lower parts of the abdomen.

Approximately 50%-80% of all individuals with Fraser syndrome have abnormalities of the genitalia. Affected females may have partial or complete fusion of the labia, the folds of skin on either side of the vagina;

an abnormally large clitoris; a malformation of the fallopian tubes, the paired tubes that connect the ovaries to the uterus; and/or an abnormally shaped uterus. Affected females beyond puberty may not have a menstrual cycle. Affected males may have undescended testicles, a condition where one or both testicles may fail to descend into the scrotum; hypospadias, a condition where the urinary opening is on the underside of the penis rather than at the tip; micropenis, an abnormally small penis; and/or urethral atresia, a condition where the urinary opening of the penis may be fused completely closed.

Another complication of Fraser syndrome is malformations of one or both kidneys. These malformations may include renal dysplasia, hypoplasia, or renal agenesis, conditions in which one or both kidneys may be small, located in the wrong place, or completely absent.

Both the navel and the nipples may develop in irregular locations. The navel can be located lower than normal and the nipples are generally wider set. A hairline that extends forward over the temples is an additional cosmetic symptom of Fraser syndrome.

Many infants with Fraser syndrome have hydrocephaly, a condition in which too much cerebrospinal fluid (CSF) collects in the brain. Some cases have been found in which the left ventricle, one of the normal cavities within the brain, is not present. Dandy-Walker malformation, an abnormal condition of the brain in which the fourth ventricle of the brain may become blocked and too much CSF collects, has also been associated with Fraser syndrome. These brain abnormalities can all cause developmental delays and intellectual disability.

Diagnosis

The symptoms of Fraser syndrome have been classified into four major and eight minor characteristics. A patient is diagnosed with Fraser syndrome rather than another genetic syndrome by the presence of at least two of the four major characteristics of the syndrome accompanied by at least one of the eight minor characteristics of the syndrome, or by the presence of one major characteristic and at least four minor characteristics.

The four major characteristics of Fraser syndrome include:

- Cryptophthalmos – hidden eyes
- Syndactyly – fused or partially fused fingers and/or toes
- Genital abnormalities
- Affected sibling(s)

The eight minor characteristics of Fraser syndrome include malformations of the:

- Nose
- Ears

QUESTIONS TO ASK YOUR DOCTOR

- What treatment is available for my child?
- What other specialists will my child need to see?
- Will my child need surgery?
- Are there support groups available for children with Fraser syndrome or their parents?
- What are the chances that my next child will have Fraser syndrome?

- Voice box
- Abdominal wall (umbilical hernia)
- Kidneys (renal agenesis, atresia, or dysplasia)
- Fingers and toes (syndactyly)
- Cleft tongue (or other oral clefts)
- Developmental/intellectual disability

Prenatal diagnosis of Fraser syndrome is possible as early as 18 weeks of fetal development and is accomplished by the observance via ultrasound of a combination of some or all of the following conditions: blockage of urine flow out of the bladder; small eyes; fused or partially fused fingers and/or toes; pulmonary obstruction, a blockage of the lungs resulting from an absence or closure of the voice box (laryngeal atresia); ascites, the accumulation of thin, watery fluid, called serous fluid, in the abdominal cavity; fetal hydrops, a blood disorder that prevents proper formation of the hemoglobin, the oxygen carrying part of blood; nuchal edema, a presence of an abnormally high amount of fluid in the tissues comprising the nape of the neck; and oligohydramnios, an absence of amniotic fluid due to an incomplete development of the kidney.

A molecular genetic test for mutations in the *FREM2* gene is available as of 2021. The test can be performed on a sample of amniotic fluid, fetal blood, fresh tissue, bone marrow, or a buccal swab.

Treatment and management

Genetic counseling is particularly important in the prenatal treatment and management of Fraser syndrome. This is because the severity of symptoms and appearance of an infant with this syndrome is likely to be very similar in a sibling also born with the disease.

Surgery is almost always necessary to correct the improperly fused tissues of the eyelids, ears, nose, and genitals. Most affected individuals are blind at birth; however, if some visual function is observed to be present such as a wincing reaction to strong light, partial vision is possible

after surgery to repair the damaged eyelids. Recently, corneal transplant surgery has been used to achieve improvements in vision. In cases of anophthalmia, missing eye(s), reshaping of the eye socket may be necessary and a glass eye is fitted for cosmetic purposes. Many infants diagnosed with Fraser syndrome are also deaf or partially deaf at birth. Special programs for the hearing and vision-impaired are necessary for these affected persons.

The most serious and life-threatening abnormalities associated with Fraser syndrome are those of the kidneys and the larynx. In some cases, the laryngeal malformations cannot be repaired, which leads to either stillbirth or death shortly after birth. This is particularly true of laryngeal atresia. Corrective surgery is often possible in cases of laryngeal stenosis, narrowing of the larynx.

If both kidneys are absent, renal agenesis, the affected individual is usually stillborn. In cases of unilateral renal agenesis, renal dysplasia, or renal hypoplasia, the affected individual may require kidney dialysis or a kidney transplant. The abnormalities of the small intestine that are associated with Fraser syndrome are generally correctable through surgery.

Prognosis

The type and severity of the kidney and voice box malformations that may result in Fraser syndrome usually determine the prognosis. Overall, 25% of all babies born with Fraser syndrome are stillborn. Another 20% die within the first year of infancy, often in the first few weeks of life. The cause of death is usually lack of kidney function or blockage of the larynx. Kidney and larynx defects tend to be either very slight or absent in the surviving 55% of Fraser syndrome affected individuals, but developmental delay is observed in most patients.

Freeman-Sheldon syndrome

Definition

Freeman-Sheldon syndrome (FSS) is a very rare genetic disorder characterized by an abnormally small puckered mouth (microstomia), which gives the appearance of a person whistling. For this reason, Freeman-Sheldon syndrome is also known as whistling-face syndrome. FSS

may also be referred to as Freeman-Burian syndrome; distal arthrogryposis type 2A (DA2A); windmill-vane hand syndrome; or craniocarpotarsal dystrophy. It is considered the most severe form of a group of disorders known as the distal arthrogryposes. FSS has also been defined as a congenital myopathy, which means that weakness of the skeletal muscles in affected children is present from birth.

Description

Ernest Freeman and Joseph Sheldon, two British physicians, first described this distinctive disorder in 1938. The syndrome is characterized by skeletal malformations in the hands and feet as well as facial abnormalities.

In addition to the small mouth, characteristics of FSS include a flat, mask-like face; underdeveloped nose cartilage; abnormally widely spaced eyes (hypertelorism); an abnormally small jaw (micrognathia); contracted muscles (contractures) in the joints in the fingers and hand; permanently bent fingers (camptodactyly); and clubbed feet. Most of the features of FSS are caused by muscle weakness. In addition to those characteristics, individuals with FSS may have crossed eyes, drooping upper eyelids (ptosis), scoliosis, hearing loss, and walking difficulties. In one case series, 80% of the children diagnosed with FSS required assistive devices (canes, walkers, etc.) in order to walk. Health is generally good, and life expectancy is normal; however, about 31% of children with FSS suffer from mild mental retardation.

Freeman-Sheldon syndrome: pedigree analysis chart (Gale)

KEY TERMS

Arthrogryposis (plural, arthrogryposes)—The medical term for joint contractures in two or more areas of the body. The English word is derived from two Greek words that mean “joint” and “curving” or “hooked.”

Camptodactyly—A congenital disorder in which one or more fingers are permanently bent. It is a classic sign of FSS as well as of several other genetic syndromes.

Congenital—Present at birth.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

De novo mutation—A genetic mutation that is not inherited from either parent.

Distal—Referring to body parts that are furthest from the center of the body.

Dysphagia—Difficulty in swallowing.

Electromyography (EMG)—A diagnostic test of the responsiveness of skeletal muscle that involves placing electrodes either on the skin above a muscle or in the muscle, and measuring the electrical activity in the muscle. The level of activity is recorded on a monitor.

Hypertelorism—Abnormally widely spaced eyes.

Malignant hyperthermia—A rare potentially fatal condition triggered by exposure to certain inhalational anesthetics, in which the body’s metabolism speeds up and overwhelms its ability to regulate body temperature.

Micrognathia—An abnormally small jaw.

Microstomia—The medical term for an abnormally small mouth.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Myopathy—The general medical term for weakness of the skeletal muscles present in the muscle tissue itself rather than in the nerves supplying the muscles.

Myosin—Any of a family of proteins involved in muscle contraction, cell movement, and other motor processes.

Ptoxis—Drooping of the upper or lower eyelid.

Scoliosis—An abnormal side-to-side curvature of the spine.

Genetic profile

FSS has several different inheritance patterns. In many cases, the syndrome follows an autosomal dominant inheritance pattern. With this pattern of inheritance, the syndrome appears when a child inherits one defective gene from one parent. In some families, however, FSS follows an autosomal recessive inheritance pattern. In these cases, the condition appears only when a child receives the same defective gene from each parent. This syndrome can also occur sporadically, that is, neither parent passes on the gene responsible for FSS. These cases of FSS result from *de novo* mutations.

In 2006, mutations in the *MYH3* gene on the short arm of chromosome 17 at 17p13.1 were identified as the cause of most cases of FSS. This gene codes for a protein that belongs to the family of myosins, which are proteins involved in cell movement and muscle contraction. Mutations in the *MYH3* gene interfere with normal development of muscle tissue in the fetus, leading to the myopathy, contractures, arthrogryposis, and other signs of FSS.

There are also a few reported cases of FSS in which there is no mutation in the *MYH3* gene. The cause of these cases was unknown as of 2021.

Demographics

Freeman-Sheldon syndrome is extremely rare; about 100 cases have been reported in the medical literature since the disorder was first described in 1938. The frequency is estimated at less than one person per million. It affects males and females in equal numbers. As far as is known, FSS affects children in all races and ethnic groups; cases have been reported in Japan, Morocco, Turkey, and India as well as Europe and North America.

Signs and symptoms

Doctors can recognize Freeman-Sheldon syndrome at birth. Babies born with FSS usually have distinct abnormalities of the head, face, hands, and feet.

Facial abnormalities usually include an extremely small and puckered mouth, a full forehead, prominent cheeks, and thin, pursed lips. The middle part of the face may be flat, giving the baby a mask-like appearance. There may be a high palate, unusually small jaw, abnormally small tongue, and a raised mark or dimpling in the shape of an “H” or “V” on the chin. Other common facial abnormalities associated with FSS include widely

QUESTIONS TO ASK YOUR DOCTOR

- How will FSS affect my child's quality of life?
- Are we likely to have a second child with the syndrome?
- What are the treatment options?
- Will my child always need to use a walker or cane in order to walk?

spaced, deep-set eyes (hypertelorism), crossed eyes (strabismus), and down-slanting eye openings.

Infants born with FSS may have malformations of the hands or feet, including clubbed feet. The muscles in the joints of the fingers and hands may be contracted.

Characteristics of FSS are often linked with other problems such as impaired speech, swallowing and eating difficulties (dysphagia), failure to thrive, and vomiting. Children may fail to grow and gain weight at the expected rate, and there may be respiratory problems. Although most of the characteristics of FSS will be discovered fairly early in life, scoliosis (curvature of the spine) may be diagnosed later in childhood or adolescence as the child grows.

Diagnosis

Because many of the characteristics of FSS are present at birth, doctors can recognize and diagnose FSS following birth based on these characteristics. Other diagnostic techniques that have been used after birth to evaluate infants whose congenital defects are less obvious include CT scanning of the head to indicate the presence and severity of craniofacial and dental abnormalities. Electromyography may be used to evaluate the strength of the muscles in the hands, feet, and jaw. FSS has also been diagnosed prenatally using ultrasound imaging.

Molecular genetic testing for mutations in the *MYH3* gene was available as of 2015 in Europe as well as in the United States. Because FSS can run in families, parents of children with FSS may wish to seek genetic counseling.

Treatment and management

Most children with Freeman-Sheldon syndrome require orthopedic or plastic surgery to correct their hand problems, clubbed feet, and tight mouth. Plastic surgery can improve the function and appearance of the mouth and nose. Craniofacial surgery can reshape the frontal bone and increase eyelid openings. The thumb may be repositioned to improve hand function.

A potential surgical complication in FSS patients is malignant hyperthermia—a life-threatening problem with inhaled anesthetic agents in which uncontrolled metabolism in skeletal muscle overwhelms the body's ability to regulate its temperature. A muscle biopsy prior to surgery can minimize this risk, as can a less invasive test that involves intramuscular injection of a small amount of halothane.

Children with FSS may also benefit from psychological counseling as they grow older in order to cope with the social complications that may result from their physical limitations or abnormal facial features.

Prognosis

Life expectancy for infants diagnosed with Freeman-Sheldon syndrome is normal. Infants and children with FSS may be referred to physical and speech therapists. Physical therapy may help children improve the use of their hands, and it also can improve ambulation (walking). Speech therapy may improve tongue movement, which helps speech and swallowing. Assistive devices are often recommended to aid muscular function.

Friedreich ataxia

Definition

Friedreich ataxia (FA, sometimes abbreviated as FRDA) is an inherited, progressive nervous system disorder causing loss of balance, coordination, and mobility. The disorder was first described by Nikolaus Friedreich, a German medical professor, in 1863.

Description

Ataxia is a condition marked by impaired coordination. FA is a progressive ataxia that typically starts around puberty and slowly progresses into adulthood. The nervous system is the affected system, with a deterioration of the cerebellum and peripheral sensory nerves, thus affecting both movement and sensation.

Genetic profile

FA is an autosomal recessive disorder, which means that two defective gene copies, one from each parent, must be inherited in order to develop symptoms. A person with only one defective gene copy is called a carrier and will not show signs of FA, but he or she has a 50% chance of passing along the gene to offspring with each pregnancy. Couples in which both parents are carriers of FA have a 25% chance with each pregnancy of conceiving an affected child.

The gene for FA is called *FXN*. It is located on chromosome 9 and codes for a protein called frataxin. Normal frataxin is found in the cellular energy structures called mitochondria, where it is involved in regulating the transport of iron. Due to the role that mitochondria have in the life of a cell, a decrease or dysfunction of this protein will result in cell death. Cell death occurs more frequently in the cells of the peripheral (outside of the brain) nervous system, which is why this disorder is classified as a nervous system disorder.

In approximately 96% of patients with FA, both copies of the frataxin gene are expanded with nonsense information known as a triple repeat of a particular sequence of DNA bases called GAA. Normally, the GAA base sequence is repeated between six and 30 times, but those with FA have between 100 and 1,300 copies. About 4%

A businessman with Friedreich ataxia and hand degeneration text-messaging on a mobile phone. (*Disability Images/Science Source*)

of patients have been found to have the triple repeat in only one copy of the frataxin gene and a different gene change in the other copy. Longer GAA repeats are generally associated with more severe disease, but the severity of disease in a particular individual cannot be predicted from the repeat length. The extra DNA or other gene change interferes with normal production of frataxin, thereby impairing iron transport. FA symptoms are thought to develop at least in part because defects in iron transport prevent efficient use of cellular energy supplies. Extra iron builds up in the mitochondria, leading to the accumulation of damaging chemicals called free radicals.

The nerve cells that are most affected by FA are those in the spinal cord involved in relaying information between muscles and the brain. Tight control of movement requires complex feedback among the muscles promoting a movement, those restraining it, and the brain. Without this control, movements become uncoordinated, jerky, and inappropriate for a desired action.

Demographics

FA is the most common inherited ataxia, affecting between one in 22,000 to one in 50,000 people or roughly 3,000 to 5,000 people in the United States. It is found in individuals of European, Middle Eastern, and North African descent and is rare in other ethnic groups. Approximately 1% of Caucasian individuals carry one defective copy of the gene for frataxin. Approximately 25% of individuals diagnosed with FA are later diagnosed with diabetes mellitus.

Signs and symptoms

Symptoms of FA usually first appear between the ages of eight and 15, although onset as early as 18 months or as late as 40 years is possible. The first symptom is

KEY TERMS

usually gait incoordination. For instance, a child with FA may graze doorways when passing through, trip over low obstacles, or show general clumsiness when walking. Unsteadiness when standing still and deterioration of position sense are common. Foot deformities and walking off the heels (toe walking) often result from uneven muscle weakness in the legs. Muscle spasms and cramps may occur, especially at night.

Ataxia in the arms usually follows within several years, leading to decreased hand-eye coordination. Arm weakness does not usually occur until much later. Speech and swallowing difficulties are common. The loss of reflexes in the lower legs is common. Diabetes mellitus, a condition characterized by elevated blood sugar, may also occur. Nystagmus, or eye tremor, is common in FA, along with some loss of visual acuity. Hearing loss may also occur. A side-to-side curvature of the spine (scoliosis) occurs in many cases and may become severe.

Heart muscle enlargement (cardiomyopathy) with or without heartbeat abnormality occurs in between half and two-thirds of FA patients, leading to shortness of breath after exertion, swelling in the lower limbs, and frequent complaints of cold feet.

There are some atypical forms of FA. For example, a portion of the Acadian population, who originated in northern France and now live in parts of Canada and Louisiana, have a very slowly progressing form of the disorder and only occasionally have heart problems, leading them to live longer than most patients with FA. Other forms include late-onset Friedreich ataxia (LOFA), in which symptoms begin after age 25, and Friedreich ataxia with retained reflexes (FARR). All three of these forms have been shown to result from changes in the same gene as the “classic” form. There have been a few patients with classic FA described in whose cases the frataxin gene on chromosome 9 has been shown not to be the cause. A form of ataxia caused by a gene change resulting in vitamin E deficiency, but having similar symptoms to FA, has been identified with changes in a different gene on chromosome 8.

Diagnosis

Diagnosis of FA involves a careful medical history and thorough neurological exam. Lab tests include electromyography, an electrical test of muscle, and a nerve conduction velocity test. An electrocardiogram may be performed to diagnose heart arrhythmia.

Direct DNA testing is available, allowing FA to be more easily distinguished from other types of ataxia. This testing is accomplished by counting the number of GAA repeats in the frataxin gene to see whether there is a significant expansion and by looking for other gene changes in patients who only show a GAA expansion in one copy of the frataxin gene. The same genetic test may be used to determine the presence of the genetic defect in the carrier state (i.e., one normal copy and one defective copy of the frataxin gene) in unaffected individuals, such as adult siblings, who would like to learn their chances of producing an affected child. During pregnancy, the DNA of a fetus can be tested using cells obtained from a procedure called chorionic villi sampling (CVS), in which cells from the placenta are studied, and amniocentesis, in which skin cells from the amniotic fluid surrounding the baby are tested.

Treatment and management

As of 2021, studies had been inconclusive concerning medical treatment of FA, but progress had been made in the management of symptoms caused by FA. Physical and occupational therapy are used to maintain range of motion in weakened muscles. Adaptive techniques and devices can be used to compensate for loss of coordination and strength. Some patients find that using weights on their arms can help to dampen the worst of their uncoordinated arm movements.

Heart problems and diabetes are treated with drugs specific to those conditions.

Prognosis

Clinical trials for FA, including a phase 2 trial of the experimental drug elamipretide, began in 2021. This drug helps to restore the ability of mitochondria to produce energy. It is being tested on people with FA and symptoms of vision and heart deterioration. Participation in U.S. clinical trials is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>.

The rate of progression of FA is highly variable. Most patients lose the ability to walk within 15 years of symptom onset, and 95% require a wheelchair for mobility by age 45. Reduction in lifespan from FA

QUESTIONS TO ASK YOUR DOCTOR

- How often should I be evaluated for progression?
- Aside from a neurologist, what doctors should I see regularly?
- Is there genetic screening to determine whether my future children will inherit this disorder?
- What is my life expectancy?
- Are there any activities I should avoid?
- How fast do you think my ataxia will progress?
- What are the ways I can increase my life expectancy (such as diet, nutrition, or exercise)?

complications, usually cardiac, is also quite variable. Average age at death, usually from heart problems, is in the mid-30s, but some may live into their mid-60s. The particular length of the triple repeat has not been correlated strongly enough with disease progression to allow prediction of the course of the disease on this basis.

Frontonasal dysplasia

Definition

Frontonasal dysplasia (FND), also called median cleft syndrome, is a rare genetic disorder that affects the prenatal development of the face and head. There are at least three different types of FND that have different signs and symptoms and are caused by mutations in different genes.

Description

The term *frontonasal dysplasia* was first used in 1970 to describe disorders characterized by at least two of the following features:

- widely spaced eyes (hypertelorism)
- a broad nose
- a cleft (slit) on one or both sides of the nose
- absence of the skin that forms the tip of the nose
- a central cleft affecting the nose, upper lip, and/or palate (roof of the mouth)
- incomplete formation of the front of the skull
- a "widow's peak" hairline—a hairline that extends farther than normal and comes to a point in the center of the forehead

FND may include:

- other facial malformations
- absence or malformation of the corpus callosum that connects the left and right brains
- intellectual disability

Additional characteristics distinguish the different types of FND:

KEY TERMS

ALX—Gene family encoding transcription factors that are required for normal prenatal development of the head and face; mutations in the *ALX1* gene cause frontonasal dysplasia (FND) type 3; mutations in *ALX3* cause FND1; mutations in *ALX4* cause FND2.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disorder.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disorder.

Hypertelorism—Abnormally wide spacing of the eyes.

Philtrum—The vertical groove on the median line of the upper lip.

Transcription factors—Proteins that regulate the activity (transcription) of specific genes.

- FND1 causes nose abnormalities, an elongated area between the nose and upper lip (the philtrum), and drooping upper eyelids (ptosis).
- FND2 can cause hair loss (alopecia) and an enlarged parietal foramen (the opening in the two bones making up the top and sides of the skull). Males with FND2 often have genital malformations.
- FND3 is associated with the most severe facial abnormalities, although severity varies widely. In general, FND3 is characterized by missing or very small eyes (anophthalmia or microphthalmia, respectively) and low-set backward-facing ears.

Genetic profile

FND is caused by mutations in different *ALX* genes.

- FND1 is caused by mutations in the *ALX3* gene, located on the short arm (p) of chromosome 1 at 1p13.3.
- FND2 is caused by mutations in the *ALX4* gene on chromosome 11 at 11p11.2.
- FND3 is caused by mutations in the *ALX1* gene located on the long arm (q) of chromosome 12 at 12q21.

ALX stands for “aristaless-like homeobox.” *ALX* genes produce proteins called transcription factors that regulate the activities (protein production) of other genes by binding to DNA. Specifically, these transcription factors control genes that produce proteins that are necessary for regulating cell growth, division, and movement

(migration). This ensures that cells grow and stop growing correctly and migrate to their proper positions during development. *ALX3* and *ALX4* proteins are important for the development of the nose and surrounding tissues. *ALX1* protein is important for development of the nose, mouth, and eyes. Mutations in these genes reduce or eliminate functioning of their respective proteins, which disrupts the organization of cells during the development of the head and face, especially the middle of the face. The facial clefts result from abnormal development of the nose, philtrum, and upper lip, which can also interfere with the formation of the skull and other facial features.

FND1 and FND3 are inherited in an autosomal recessive pattern. This means that two mutated *ALX* genes, one inherited from each parent, are required to develop the disorder. The parents, with one mutated gene each, typically have no signs or symptoms of FND, because they have a second normal *ALX* gene.

FND2 is inherited in an autosomal dominant pattern, so that the condition develops in a fetus that has only one mutated *ALX4* gene and one normal *ALX4* gene. The mutated gene may have been inherited from an FND-affected parent or may have arisen by spontaneous mutation in the egg, sperm, or early embryo, in the absence of a family history of FND. FND1 and FND3 can also be caused by sporadic mutations. Genetic testing is available for *ALX* gene mutations.

Demographics

FND is believed to be very rare, although more than 100 cases have been reported in the medical literature. It has not been associated with any particular ethnic or social group. Some reports indicate that FND is more common in males than in females and that it is associated with increased parental age, which may increase the risk of sporadic gene mutations in egg or sperm cells.

Signs and symptoms

In addition to the characteristics described, severe FND may include a vertical groove down the middle of the face, which, in the most extreme instances, may cause the nose to vertically separate into two parts (median cleft nose). Malformation of the bony structures (orbits) that hold the eyeballs can cause vision defects and even blindness.

A group of heart abnormalities known as the tetralogy of Fallot has been observed in a few cases of FND. This is a combination of four heart disorders: an abnormal narrowing of the valve that opens from the right ventricle of the heart into the pulmonary artery (pulmonary stenosis); a hole or perforation in the wall between the left and right ventricles of the heart that allows blood to flow

QUESTIONS TO ASK YOUR DOCTOR

- What type of frontonasal dysplasia does my child have?
- What surgeries does my child require?
- What is my child's prognosis?
- What is my risk of having another child with frontonasal dysplasia?
- Is preimplantation or prenatal genetic screening available for frontonasal dysplasia?

directly from the higher-pressure left ventricle to the lower-pressure right ventricle (ventricular septal defect); abnormal positioning of the aorta on the right rather than the left side of the heart (dextroposition of the aorta), which means that blood flows out of the right ventricle into the aorta so that deoxygenated blood rather than oxygenated blood is delivered to the body; and finally, an abnormally large right ventricle (hypertrophy of the right ventricle), which is generally associated with the three other anomalies, since each of these overburdens the right ventricle. This set of conditions leads to poor oxygenation of the blood, causing a “blue baby” at birth and requiring immediate surgery.

Skeletal deformities have been observed in some cases of FND. These include the presence of an extra toe arising from the great toe (hallucal polydactyly) and severe underdevelopment of the major bone of the shin (tibial aplasia).

Brain anomalies can include the absence of the corpus callosum connecting the left and right hemispheres of the brain and swelling or hernias in the brain (basal encephalocele). When intellectual disabilities occur, they appear to be associated with the degree of hypertelorism: the greater the distance between the eyes, the greater the likelihood of developmental delays.

Diagnosis

Frontonasal dysplasia is generally diagnosed at birth based on the observed facial abnormalities. The presence of two or more of the following symptoms is considered a positive diagnosis:

- a skin-covered gap in the bones of the forehead (anterior cranium bifidum occultum)
- hypertelorism
- median cleft lip
- median cleft nose

- any abnormal development of the center (median cleft) of the face

FND may be diagnosed prenatally by ultrasound observations of craniofacial deformations (holoprosencephaly). It can also be diagnosed prenatally by genetic testing if the relevant gene mutation(s) in the family have been identified.

Treatment and management

Cosmetic surgery can correct at least some of the facial defects associated with FND. Multiple surgeries may be required for severe cases. Surgeries include reformation of the eyelids (canthoplasty), reformation of the orbits (orbitoplasty), surgical positioning of the eyebrows, and plastic surgery of the nose (rhinoplasty).

In cases of congenital heart defects, corrective surgery is required shortly after birth.

Surgery can remove an extra toe and correct underdevelopment of the tibia (shin bone). The tibia supports five-sixths of the body weight when standing, with the smaller fibula supporting the remaining one-sixth. If surgery is not performed to correct shin-bone defects, the individual may never be able to stand or walk.

In the rare cases of FND-associated intellectual impairment, early and ongoing intervention is necessary.

Prognosis

Life expectancy depends on the severity of the FND and whether surgeries can improve problems such as breathing and eating difficulties caused by the facial clefts. However, most individuals with FND are of average intelligence and can expect a normal lifespan. In the rare cases of associated heart abnormalities, the infant may die shortly after birth if corrective surgery is not performed immediately.

Frontotemporal dementia

Definition

Frontotemporal dementia (FTD) is one of a group of conditions that cause progressive degeneration of the anterior temporal lobe, the decision-making and behavior control center of the brain; and the frontal lobe, the language and emotion control center of the brain. Dementia is not a disease in itself but is a general term used to describe the loss of the ability to think, reason, and remember, all symptoms that may accompany a wide variety of conditions and diseases.

Description

Although less common than Alzheimer’s disease, the most common of the dementias, FTD is the third most common form of dementia.

Arnold Pick, a neuropsychiatrist, identified the first type of FTD in the early 1890s, when he noticed the dramatic shrinkage in the frontal and temporal brain regions during the autopsies of some people with a dementia. This shrinkage seriously disrupted the ability of these individuals to use language.

In later examinations of Pick’s tissue samples, the pioneer neuropathologist Alois Alzheimer, who was the first to identify Alzheimer’s disease, observed that the shrunken brain regions showed similar microscopic changes. Some nerve cells appeared swollen; others contained spherical abnormalities. Later, the swollen cells became known as Pick’s cells; the tiny spheres were called Pick’s bodies; and the disorder itself became known as Pick’s disease.

As scientists acquired more knowledge of brain pathology, they observed that in some cases of FTD degeneration, Pick’s cells or bodies were not present. During the 1970s and 1980s, new diagnostic imaging techniques revealed that frontotemporal degeneration comprised a wide variety of symptoms aside from language difficulties. Imaging studies also suggested that frontotemporal disease is more common than was originally believed, representing up to 20% of dementia cases.

A combination of all of these factors, including reduced emphasis on Pick’s abnormalities, varied symptoms, and newly recognized frequency, contributed to an expanding list of names for frontotemporal disorders. To help clarify the situation, researchers adopted the term *frontotemporal dementia* to encompass all the disorders resulting from gradual deterioration of the frontal and temporal regions of the brain. Sometimes, however, the terms Pick’s disease, FTD, and frontotemporal lobar degeneration (FTLD) are used interchangeably.

In general terms, damage to cells in the temporal lobe appears to produce language and emotional dysfunction. Patients with the most severe damage to the frontal lobe experience more severe problems with decision-making function and behavior. Initially, the damage may occur on just one side of the brain. In most cases, however, as the disease progresses, both sides of the brain are affected.

Frontotemporal dementia most commonly refers to a group of specific disorders. These include:

- **Pick’s disease:** A rare brain disease that is characterized by shrinkage of the tissues of the brain’s frontal and temporal lobes and the presence of small deposits (Pick’s bodies) in the nerve cells of the affected area. Pick’s bodies are not always present in FTD. The disease resembles Alzheimer’s disease in the personality changes and disorientation that may precede memory loss.
- **Corticobasal degeneration:** A progressive neurologic disorder that is characterized by nerve cell loss and shrinkage of multiple areas of the brain, including the cerebral cortex and basal ganglia. Symptoms like rigidity and loss of muscle coordination resemble those symptoms found in Parkinson’s disease.
- **Progressive aphasia:** A rare neurologic disorder that is characterized by progressively impaired language

abilities, although other mental functions and activities of daily living are preserved.

- **Semantic dementia:** Also known as fluent progressive aphasia, semantic dementia is a language disorder in which patients exhibit a progressive deterioration of the understanding and recognition of words, although impairment in other cognitive faculties is not present.
- **Frontotemporal dementia with Parkinsonism-17 (FTDP-17):** A type of progressively worsening dementia that involves the frontal and temporal areas of the brain, and is characterized by behavioral and cognitive changes, psychiatric symptoms, language difficulties, and Parkinsonian symptoms, such as tremor and muscle rigidity. This form of FTD is linked to the *MAPT* gene on chromosome 17.
- **Frontotemporal dementia with motor neuron disease (FTD-MND):** A disorder in which FTD coexists with MND and primarily affects the temporal lobe of the brain; also known as amyotrophic lateral sclerosis (ALS, or Lou Gehrig's disease) with dementia or ASL-FTD. ALS is a neuromuscular disease that progressively weakens and destroys motor neurons, the cells in the nervous system that send messages from the brain to the rest of the body.

Genetic profile

Frontotemporal dementia may be sporadic, occurring in one family member; familial, involving two or more family members; or hereditary. In most cases, about 60%, FTD is sporadic. When FTD is diagnosed in a person with no family history of FTD or dementia, the isolated or sporadic case appears to pose no increased risk to family members.

About 40% of FTD cases are believed to have a genetic component, such as a positive family history for FTD or a related neurodegenerative condition or dementia. Of those, about 10% have mutations in the *MAPT* gene, which is located on chromosome 17. The children of a person with a mutation in this gene have a 50% chance of inheriting that same disease-causing mutation. Researchers have found some linkage to chromosome 9 and some to chromosome 3, and other FTD genes are likely to be found in the future.

The *MAPT* gene is responsible for the instructions for making a protein called tau protein. Tau protein is found throughout the nervous system and in the brain. These proteins are integral in producing the internal framework of cells including neurons. Tau helps to build and secure structures within the cell called microtubules which help cells maintain their shape, move materials inside the cell membrane, and divide. Mutations in the *MAPT* gene cause the tau proteins to malfunction and begin to form abnormal clumps within cells. These

clumps cause cells to die. Researchers are not sure why, but when an individual has mutations in the *MAPT* gene, neurons in parts of the frontal and temporal lobe of the brain begin to die, causing the symptoms of FTDP-17.

FTDP-17 is one of several conditions known as the tauopathies because they all involve an abnormal clumping of tau proteins within the brain. FTDP-17 is inherited in an autosomal dominant pattern, meaning that only one copy of the mutated gene is necessary to cause the condition.

About 5%–10% of patients have a family history that suggests a hereditary condition with an autosomal dominant pattern of inheritance, meaning that there is a clear pattern of FTD-type diagnoses being passed from parent to child, with virtually every patient having an affected parent, and each child of an affected person having a 50% chance of inheriting the disorder. Only one of the subtypes, FTDP-17, is exclusively hereditary.

FTD has been linked to two additional known genetic mutations. Mutations in the *GRN* and *CHMP2B* genes are known to cause FTD. The *GRN* gene on chromosome 17 is responsible for making a protein called granulin or progranulin. Granulin is present in many tissues and is important in controlling growth and survival of cells. Granulin is active in the brain. Though it is still unclear how, granulin appears to be significant in the survival of nerve cells called neurons. Mutations in the *GRN* gene prevent granulin from forming in sufficient quantities. When there is not enough granulin in the brain, it is associated with a buildup of a protein called TAR DNA-binding protein (TDP-43). Researchers have discovered that when TDP-43 accumulates in the brain it forms clumps that inhibit neuron function and ultimately leads to cell death. The symptoms of FTD occur when the neurons in the frontal and temporal regions of the brain begin to die as the TDP-43 clumps accumulate in those regions. Researchers have not yet discovered why the neurons in these regions are susceptible to the abnormal TDP-43. FTD caused by this mutation is called *GRN*-related frontotemporal dementia.

The *CHMP2B* gene on chromosome 3 is responsible for helping make a protein called charged multivesicular body protein 2B. This protein works in the brain to remove proteins that need to be broken down. Mutations in the *CHMP2B* gene cause this protein to be formed abnormally so that it cannot transport and degrade proteins. This failure leads to the death of neurons and causes the symptoms of *CHMP2B*-related frontotemporal dementia.

Both *GRN* and *CHMP2B* FTD are inherited in an autosomal dominant pattern, meaning that only one copy of the mutated gene is necessary to cause the condition. In most cases of these types of FTD, an affected individual has at least one parent and one other family member with the same condition.

Researchers have also identified a type of FTD associated with ALS. Doctors first considered ALS a disease of the body not necessarily involving dementia; however, as more people with ALS were treated and studied, it became apparent that a percent of those patients were experiencing symptoms of dementia that are very similar to those of FTD.

Several genetic mutations have been found that correspond with combined symptoms of ALS and FTD, a condition known as ALS-FTD. Mutations in the following genes have been identified in known cases of ALS-FTD:

- **ANG**—The *ANG* gene on chromosome 14 is responsible for coding instructions for producing a protein called angiogenin, which helps new blood vessels grow from existing blood vessels. In individuals with ALS, the *ANG* gene is more likely to be mutated in multiple ways. Researchers theorize that these mutations reduce the activity of angiogenin and lead to the death of neurons. Patients with *ANG* mutations are more likely to have symptoms of ALS along with symptoms of FTD.
- **C9orf72**—The *C9orf72* gene on chromosome 9 is responsible for producing a little understood protein found within the brain. This protein is found in neurons both in the cytoplasm, the fluid inside the cell, and at the presynaptic terminals, or specialized cells at the tips of neurons. Mutations of this gene are known to cause ALS, and individuals with this mutation are more likely to have ALS-FTD.
- **DCTN1**—The *DCTN1* gene on chromosome 2 provides instructions for making a protein called dynactin-1. Two versions of this protein are found within neurons. These proteins join with other proteins to form a protein complex called the dynactin complex, which is important in the formation of microtubules that create a pathway for materials to move within a cell. Researchers have discovered several mutations in the *DCTN1* gene that are associated with an increased risk of developing ALS. Individuals with this type of ALS also have an increased risk of developing ALS-FTD.
- **FUS**—The *FUS* gene on chromosome 16 provides instructions for making a protein called fused in sarcoma (FUS). This protein is involved in the process of transcription, the first step in the series by which DNA transfers information to produce RNA. Specifically, the FUS protein is important in producing messenger RNA, which carries the instructions necessary for transcription to be completed. There are more than 50 mutations in the *FUS* gene that are known to cause ALS. In individuals with these mutations, some also develop ALS-FTD.
- **TARDBP**—The *TARDBP* gene on chromosome 1 provides instructions for making a protein called transactive response DNA binding protein 43 kDa (TDP-43), which is important in the process of transcription. TDP-43 has

been found in the nucleus of many different tissue cells. The *TARDBP* gene is especially active during fetal development and is important in the formation of neurons and internal organs. Much like mutations in the *FUS* gene, more than 50 different mutations in the *TARDBP* gene have been linked to ALS. Researchers believe that these mutations cause the TDP-43 protein to form clumps and that these clumps cause neurons and muscle tissue to die. Individuals with known mutations in the *TARDBP* gene are more likely to have ALS-FTD.

- Other genes that have been linked to ALS-FTD as of 2021 include the *CYLD* gene on chromosome 16; the *OPTN* gene on chromosome 10; the *SQSTM1* gene on chromosome 5; and the *TBKI* gene on chromosome 1.

Demographics

It is estimated that as many as seven million Americans may be affected with some form of dementia, and FTD may account for about 25% of those dementias. FTD occurs most frequently between the ages of 35 and 75, and was believed to affect men and women equally. Recent studies, however, have indicated that FTD appears to be more common in men and is a more common cause of early-onset dementia than previously recognized.

Signs and symptoms

FTD comprises a wide variety of symptoms that vary widely from person to person, depending on the degree of involvement of the frontal and temporal lobes and the side of the brain affected.

Although two major symptom patterns emerge in all forms of FTS, namely gradual and progressive changes in behavior and language, some symptoms are more closely associated with one subtype of FTD than another. In general, the range of symptoms associated with FTD includes behavioral, linguistic, cognitive, emotional, neurologic, and psychiatric.

A progressive deterioration in the ability to control or adjust behavior appropriately in different social contexts is the characteristic feature of all the behavioral changes. This results in embarrassing social situations that can be one of the most disturbing aspects of FTD. Patients with FTD often present two seemingly opposite behavioral profiles in the early and middle stages of the disease. Some people are hyperactive, restless, distracted, and uninhibited. Others are apathetic, lack spontaneity, and are emotionally blunted.

Behavioral symptoms include:

- Compulsive behaviors involving, for example, eating, drinking, or dressing

- Repetitive behaviors, such as turning the television on and off
- Deteriorating personal hygiene habits, such as bathing, grooming, and dressing
- Hyperactive behaviors, such as pacing, agitation, aggression
- Impulsive or inappropriate behaviors involving, for example, sexual acting-out
- Changes in sleep patterns, including prolonged sleepiness, especially in those with more apathetic behaviors

Linguistic symptoms include:

- Decreasing speech to the point of total silence in some patients conversation is not spontaneous but rather mechanical
- Weak-sounding, imprecise, or incoherent speech
- Difficulties remembering the rules of English grammar and syntax
- Repetition of a word or phrase uttered by another (echolalia)
- Repetition of a word or phrase uttered by the person themselves (palilalia)
- Loss of the ability to speak

Cognitive symptoms include:

- Distractibility and impatience
- Rigid and inflexible thinking and impaired judgment
- Difficulty with abstract reasoning
- Poor financial judgment

As opposed to those affected by Alzheimer's disease, patients with FTD tend to have normal results on intelligence tests until that point in the disease process at which apathy results in lower scores.

Emotional symptoms include:

- Apathy or indifference to people and events
- Lack of understanding of self and others
- Lack of empathy toward and understanding of others, including family members and close friends
- Frequent and abrupt mood changes

Neurologic symptoms include:

- Movement dysfunction, including decreased facial expression, slow movements, rigidity, difficulties with posture, and sometimes abnormal eye movements
- Muscle dysfunction, such as weakness, muscle jerking, or atrophy

Psychiatric symptoms include:

- Depression
- Manic behavior

- Paranoia
- Visual or auditory hallucinations

Diagnosis

Although medical knowledge of FTD is still evolving and a broad range of subtypes is involved, current technology is providing the first evidence of the pathologic changes that occur in specific areas of the brain that cause FTD's varied symptoms. For example, loss of function in an individual's temporal lobe produces language changes, and loss of function in the frontal lobe appears to lead to behavioral symptoms, including aggressive, antisocial, and other socially unacceptable behaviors.

Because of its symptoms, FTD is often initially misdiagnosed as a psychiatric problem, Alzheimer's disease, or Parkinson's disease. However, there are features that rule out other diagnoses and identify features that pinpoint FTD.

Medical history

The presentation of the disorder within families can vary. Some people may have FTD alone, and others may develop Parkinsonism or psychiatric symptoms. Because of this variability, a careful analysis of family medical and social history can help clarify whether an affected person has a sporadic or a hereditary form of the disorder.

It is important to interview another source, such as a spouse, partner, or adult child, regarding changes in the patient's cognitive performance or behavior that are having a negative impact on the patient's activities of daily living. This source is important in establishing information about past performance and behavior, as well as the progression of symptoms that the patient may not be able to provide reliably. The additional source may also provide information that can be used to test the patient's recent and long-term memory. Significant functional changes in memory and other cognitive domains that interfere with everyday activities (such as driving, functioning at work, and/or interactions with family and friends) signal a disease state and are not part of the typical aging process.

It is essential to determine the potential for medication-induced confusion or dementia by studying the patient's drug inventory and looking for compounds that may cause or exacerbate any loss of mental capacity.

Physical examination

A targeted physical examination should be performed in all patients with dementia. Signs of systemic disorders, such as vasculitis, systemic lupus erythematosus (SLE, a chronic inflammatory condition), tuberculosis, and hypothyroidism, suggest that further evaluation is necessary.

KEY TERMS

Computed tomography (CT)—Imaging procedure that uses x-rays and computers to create detailed pictures of areas inside the body.

Electroencephalogram (EEG)—A test that measures the electronic waves of the brain.

Dementia—A group of disorders and symptoms that impact memory, reasoning, social abilities, and intellectual functioning and that impair the ability to function normally in daily life.

Frontal lobe—Region of the brain located in the frontal and upper cortex, it is responsible for higher mental functions like critical thinking and decision making.

Magnetic resonance imaging (MRI)—A test that uses a magnet and radio waves to take pictures of organs and structures inside the body.

Positron emission tomography (PET)—A test that uses a special type of camera and a radioactive chemical called a tracer to look at organs in the body.

Single-photon computed tomography (SPECT)—Nuclear imaging that uses gamma rays to produce 3D images of inside the body.

Temporal lobe—Region of the brain located at the bottom middle part of cortex, right behind the temples; it is responsible for processing auditory information.

Physical problems, such as profound hearing or visual loss, may exacerbate FTD.

Laboratory studies

The American Academy of Neurology practice parameters suggest that routine evaluation of a patient with dementia should include: complete blood count (CBC); serum electrolytes, including calcium; glucose; blood urea nitrogen (BUN) and creatinine; liver function tests; thyroid tests; vitamin B₁₂ level; and syphilis serology.

Neurologic examination

Neurologic examination may reveal signs that vary according to which part of the brain is affected, either the temporal or the frontal lobe, with associated behavioral and language changes. Careful neurologic examination should include observation of gait and posture, cranial nerves, motor strength, sensation, and reflexes. In more advanced stages of FTD, neurologic examination often reveals motor dysfunction and reflex abnormalities.

Neuropsychological examination

This examination assesses, for example, language, behavior, abstraction, memory, executive, motor skills, and visual-spatial functioning. There are many tools available for cognitive testing. The goal of testing is to demonstrate a decline in intellectual function, to assess whether depression is a contributing factor, to make predictions about future functioning, and to plan care. The Mini-Mental State Examination (MMSE) and the Geriatric Depression Scale may be administered by primary caregivers and should be performed on all patients with dementia. More detailed evaluation, such as the Wechsler Adult Intelligence Scale (WAIS), the Blessed Information, Memory and Concentration Test (BIMC), visuospatial testing, and the Boston Diagnostic Aphasia Evaluation, also may be helpful in making a diagnosis.

Neuroimaging studies

These studies include magnetic resonance imaging (MRI), computed tomography (CT), positron emission tomography (PET), and single-photon computed tomography (SPECT). They help to determine the exact location and extent of atrophy in the brain as well as areas of decreased blood flow. Electroencephalogram (EEG), or brain scan, results are usually normal even in advanced stages of the disease.

Although differentiating FTD from dementias, such as Alzheimer's disease, has been difficult, with more sophisticated brain imaging, such as SPECT, some researchers have claimed that they can diagnose Alzheimer's disease with an accuracy rate of nearly 100%. Differentiating among the various subtypes of FTD, however, still remains a challenge. Sometimes definitive diagnosis of these conditions can be made only by brain autopsy after death.

Treatment and management

There is no cure for FTD, and in most cases, disease progression cannot be slowed. Although no medications have been proven effective specifically for FTD, many physicians look to the medications and treatment approaches used in similar disorders to develop a therapeutic approach. For example, some patients with FTD benefit from selective serotonin reuptake inhibitors (SSRIs), which are used in treating depression; and acetylcholinesterase inhibitors, which are used in treating Alzheimer's disease to help prolong the activity of neurotransmitters in the brain. Physicians may also use antioxidants, such as vitamin E or coenzyme Q10, which are known to slow the progression of damage to brain cells in general.

FTD is progressive and after a few years, a patient's ability to live and function independently are decreased, leaving them dependent on others for activities of daily

living. Care of patients with FTD focuses on maximizing quality of life, treating neuropsychiatric complications, ensuring patient safety, and supporting and educating caregivers. It is important for caregivers and families to consider long-term management issues and identify a team of experts who can help with difficult medical, financial, and emotional challenges. Also, it is important to have a physician who is knowledgeable about FTD and comprehensive approaches to treatment. In addition, speech therapists, occupational and physical therapists, neuropsychologists, nurses, and genetic counselors may be helpful.

Prognosis

Prognosis varies, but studies have shown that a person with FTD may live with the disease an average of 8 years, with a range of 3–17 years. A more slowly progressive form of FTD occurs in the small percentage of people with familial tau-positive disease. People with FTD-MND have the shortest life expectancy, both before and after diagnosis.

Fryns syndrome

Definition

Fryns syndrome is a multiple congenital anomaly syndrome usually resulting in neonatal death.

Description

Fryns syndrome is a genetic condition involving abnormalities in many organ systems that usually results in neonatal death. The condition was first reported in 1979 by J. P. Fryns a Belgian geneticist.

Typical anomalies include a characteristic facial appearance, including a broad nasal bridge (part of the nose between the eyes), small jaw, abnormal ears, cleft palate, abnormal fingers, underdevelopment of the lungs, and abnormalities of the urogenital system (kidneys and genitals). Diaphragmatic hernia (opening in the diaphragm muscle that can allow contents of the lower abdomen like the liver or intestine or stomach to move up into the chest cavity through the hole) can also be seen in some cases. Some researchers believe that there may be a distinct subset of patients without diaphragmatic hernia who are more mildly affected.

Genetic profile

Fryns syndrome is inherited in an autosomal recessive manner. This means that two defective gene copies must be inherited, one from each parent, for the disease to manifest itself. Persons with only one gene mutation are carriers for the disorder. A person who is a carrier for Fryns syndrome does not have any symptoms and does not know he/she is a carrier unless he/she has had a child with Fryns syndrome. Carrier testing is not available since the gene location is not known at this time. The likelihood that each member of a couple would be a carrier for a mutation in the same gene is higher in people who are related (consanguineous). When both parents are carriers for Fryns syndrome, there is a one in four chance (25%) in each pregnancy for a child to have the disease. There is a two in three chance that a healthy sibling of an affected child is a carrier.

There have been several different chromosome abnormalities reported with a Fryns syndrome-like appearance. Investigation for a candidate gene causing Fryns syndrome has not yet identified the causative gene.

Demographics

The number of affected individuals is reported as 0.7% out of every 10,000 births. There does not appear to be any ethnic difference in prevalence. There are more than 50 documented cases of Fryns syndrome in the literature.

QUESTIONS TO ASK YOUR DOCTOR

- At what stage of development is it possible to diagnose Fryns syndrome? On what factors is such a diagnosis based?
- What are the characteristic features of a child with Fryns syndrome?
- What do researchers know about the genetic basis of Fryns syndrome?
- What is the prognosis for a child born with Fryns syndrome?

Signs and symptoms

The most frequent anomalies have been described as diaphragmatic defects, underdeveloped lungs, cleft lip and palate (usually on both sides, called bilateral), heart defects, cysts in the kidneys, urinary tract abnormalities, and limb underdevelopment.

Most patients also have underdeveloped external genitals, abnormal internal reproductive structures, abnormalities in the digestive tract, and abnormalities in the structure of the brain. Fewer patients have eye abnormalities.

Other reported anomalies include fetal hydrops (fluid surrounding the fetus prenatally, usually fatal), prematurity, scoliosis (curvature of the spine), extra vertebrae or ribs, abnormal bone formation, and small chest cavity.

Diagnosis

Prenatal diagnosis has been possible in several fetuses by use of ultrasound to identify in one fetus fetal hydrops, diaphragmatic hernia, and dilation of the cerebral ventricles and in another with cystic hygroma and diaphragmatic hernia. These anomalies themselves can be isolated or as a part of another genetic syndrome; it is the specific combination of anomalies that would lead one to suspect Fryns syndrome. Definitive diagnosis is not possible until after birth or autopsy.

Treatment and management

Since Fryns syndrome is a genetic disease caused by mutations in specific genes, there is no cure at this time. Some of the anomalies may be amenable to surgery, such

as diaphragmatic hernia or cleft palate, but the entire prognosis for the baby must be considered.

Special education for intellectually disabled individuals is indicated if the child survives.

Prognosis

Unfortunately, the prognosis for babies with Fryns syndrome is poor, with usual neonatal death occurring due to the lung hyperplasia and respiratory distress or other anomalies. Approximately 14% of infants survive the neonatal period. Survivors typically do not have complex heart malformations and less frequently have diaphragmatic hernias, milder lung hypoplasia, and neurologic impairment (usually severe to profound intellectual disability with serious brain malformations).

Galactosemia

Definition

Galactosemia is a type of inherited disease known as inborn errors of metabolism—in which the transformation of galactose (a simple sugar found in dairy products and human breast milk) to glucose (the form of sugar the body uses to produce energy) is blocked, allowing galactose to increase to toxic levels in the body. If galactosemia is untreated, high levels of galactose cause vomiting, diarrhea, lethargy, low blood sugar, brain damage, jaundice, liver enlargement, cataracts, susceptibility to infection, and death.

There are three main types of galactosemia:

- Classic galactosemia (galactosemia type I)—the most common and most severe type.
- Galactokinase deficiency (galactosemia type II)—less severe with fewer symptoms than classic galactosemia.
- Galactose epimerase deficiency (galactosemia type III)—the most rare form, this type of galactosemia has similar symptoms to the classic type; however, the symptoms may range from mild to severe.

Description

Galactosemia is a rare but potentially life-threatening disease that results from the inability to metabolize galactose. Lactose, the principle carbohydrate of human milk, commercial infant formulas, and other dairy products, is broken down in the human intestine into its component sugars: glucose and galactose. After absorption by the intestine, galactose is sequentially metabolized by three separate enzymes (galactokinase, galactose-1-phosphate uridylyltransferase, and galactose-4-epimerase) to convert it to glucose, a usable form of fuel for individual cells.

“Metabolism” refers to all chemical reactions that take place in living organisms. A metabolic pathway is a series of reactions in which the product of each step in

the series is the starting material for the next step. Enzymes are the chemicals that help the reactions occur. Their ability to function depends on their structure, and their structure is determined by the deoxyribonucleic acid (DNA) sequence of the genes that encode them. Inborn errors of metabolism are caused by mutations in these genes that do not allow the enzymes to function properly.

Classic galactosemia, the most common form of galactosemia, is caused by a deficiency of the second enzyme in the pathway, galactose-1-phosphate uridylyltransferase (GALT), and is typically associated with cataract formation, intellectual disability, and liver damage. Galactokinase deficiency (also known as GALK deficiency or galactosemia type II) is a rarer form of galactosemia caused by the absence of the enzyme galactokinase, which is responsible for the first step of the conversion of galactose to glucose. However, unlike the more serious form of classic galactosemia, galactokinase deficiency mainly manifests as injury to the eyes without damage to other organ systems. The third and final form of galactosemia, galactose epimerase deficiency (galactosemia type III), is the rarest of the group; few cases have been described, and the symptoms of this form of galactosemia are variable but usually mild. Serious consequences from galactosemia can be prevented by screening newborns at birth with a simple blood test.

Galactosemia may have been described in German medical publications as early as 1908; in 1917, F. Goepert noted symptoms of galactosemia in an infant and sibling, suggesting that the disorder could be inherited. In 1935, the American scientists H. H. Mason and M. F. Turner described a patient with a group of symptoms that could be prevented by removal of milk from the diet. In 1954, the individual steps in the metabolic pathway for the conversion of galactose to glucose were described by L. F. Leloir, who was later awarded a Nobel Prize in Chemistry for his efforts. Leloir’s work made it possible for scientists such as V. Schwatz and K. J. Isselbacher to demonstrate that defects in this metabolic pathway

were responsible for galactosemia and its associated symptoms.

Genetic profile

Galactosemia is caused by mutations in the *GALE*, *GALK1*, and *GALT* genes. These genes provide instructions for making the enzymes that process galactose obtained from the diet by breaking it down into glucose and other molecules that the body can store or use for energy. Mutations in the *GALT* gene on chromosome 9 at 9p13 are responsible for classic galactosemia (type I). Most mutations almost completely eliminate the activity of the enzyme produced from the *GALT* gene, resulting in the life-threatening galactosemia symptoms. Another *GALT* mutation, the Duarte variant, lowers but does not eliminate the activity of the enzyme, resulting in milder galactosemia.

Mutations in the *GALK1* gene on chromosome 17 at 17q24 are responsible for galactosemia type II, while mutations in the *GALE* gene on chromosome 1 at 1p36-p35 cause galactosemia type III. The enzymes made from the *GALK1* and *GALE* genes are also important in the breakdown of galactose. If not present, galactose and related compounds can build up to toxic levels in the body and damage tissues and organs.

Every cell in a person's body has two copies of each gene. Each of the types of galactosemia is inherited as a recessive trait, which means that galactosemia is only present in individuals with two mutated copies of one of the three genes. This also means that carriers, who only have one copy of a gene mutation, will not be aware that they are carrying a mutation unless they have had a genetic test, because it is masked by the normal gene on the second chromosome they also carry and the fact that they have no symptoms of the disease. For each step in the conversion of galactose to glucose, if only one of the

two copies of the gene controlling that step is normal (i.e., for carriers), enough functional enzyme is made so that the pathway is not blocked at that step. If a person has galactosemia, both copies of the gene coding for one of the required enzymes are defective and the pathway becomes blocked. If two carriers of the same defective gene have children, the chance of any of their children getting galactosemia (the chance of a child getting two copies of the defective gene) is 25% (one in four) for each pregnancy.

Demographics

In the United States, classic galactosemia occurs in 1 in 30,000 to 60,000 newborns. Galactosemia type II and type III are less common: type II is believed to affect fewer than 1 in 100,000 newborns and type III appears to be very rare. Worldwide, the prevalence of galactosemia is estimated at 6 per 100,000 live births.

Signs and symptoms

Galactosemia type I

Newborns with galactosemia type I appear normal at birth, but begin to develop symptoms after they are given milk for the first time. Symptoms include vomiting, diarrhea, lethargy (sluggishness or fatigue), low blood glucose, jaundice (a yellowing of the skin and eyes), enlarged liver, protein and amino acids in the urine, and susceptibility to infection, especially from gram-negative bacteria. Cataracts (a grayishwhite film on the eye lens) can appear within a few days after birth. People with galactosemia frequently have symptoms as they grow older even though they have been given a galactose-free diet. These symptoms include speech disorders, cataracts, ovarian atrophy and infertility in females, learning disabilities, and behavioral problems.

KEY TERMS

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Enzymes—Proteins within the body that cause chemical reactions such as breaking food into a form that can be used as energy.

Galactose—One of the two simple sugars, together with glucose, that makes up the protein lactose found in milk. Galactose can be toxic in high levels.

Glucose—One of the two simple sugars, together with galactose, that makes up the protein lactose found in milk. Glucose is the form of sugar that is usable by the body to generate energy.

Inborn error of metabolism—Any of a number of rare genetic disorders that inhibit the body's ability to turn food into energy.

Lactose—A sugar made up of glucose and galactose. It is the primary sugar in milk.

Metabolic pathway—A sequence of chemical reactions that lead from some precursor to a product, in which the product of each step in the series is the starting material for the next step.

Metabolism—The total combination of all of the chemical processes that occur within cells and tissues of a living body.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Newborn screening—The act of testing all infants for a specific disease shortly after birth for the purpose of preventing disease progression through prompt medical treatment.

Galactosemia type II

Galactosemia type II is less harmful than galactosemia type I. Babies born with galactosemia type II will develop cataracts at an early age unless they are given a galactose-free diet. They do not generally have liver damage or neurologic disturbances.

Galactosemia III

There are two forms of galactosemia III, a severe form, which is exceedingly rare; and a benign form. The

benign form has no symptoms and requires no special diet. However, newborns with galactosemia III, including the benign form, have high levels of galactose-1-phosphate that show up on the initial screenings for elevated galactose and galactose-1-phosphate. This situation illustrates one aspect of the importance of follow-up enzyme function tests. Tests showing normal levels of GALT and GALK allow people affected by the benign form of galactosemia III to enjoy a normal diet.

The severe form has symptoms similar to those of galactosemia I, but with more severe neurological problems, including seizures.

Diagnosis

The newborn screening test for classic galactosemia is quick and straightforward; all states in the United States and most provinces in Canada require testing on all newborns. Blood from a baby who is two to three days old is usually screened for high levels of galactose and galactose-1-phosphate. If either of these compounds is elevated, further tests are performed to find out which enzymes (GALT, GALK, or GALE) are present or missing.

DNA testing may also be performed to confirm the diagnosis. Clinical testing is available for the eight common *GALT* galactosemia (G) mutations. For individuals with Duarte variant (D/G) galactosemia identified by biochemical testing of the individual and both parents, the Duarte mutations can be identified by targeted mutation analysis.

If there is a strong suspicion that a baby has galactosemia, galactose is removed from their diet right away. In this case, an initial screen for galactose or galactose-1-phosphate will be meaningless. In the absence of galactose in the diet, this test will be negative whether the baby has galactosemia or not. In this case, tests to measure enzyme levels must be given to find out if the suspected baby is indeed galactosemic.

In addition, galactosemic babies who are refusing milk or vomiting will not have elevated levels of galactose or galactose phosphate, and their condition will not be detected by the initial screen. Any baby with symptoms of galactosemia (for example, vomiting) should be given enzyme tests.

Treatment and management

Galactosemia type I and type II are treated by removing galactose from the diet. Since galactose is a breakdown product of lactose, the primary sugar constituent of milk, this means all milk and foods containing milk products must be totally eliminated. Other foods like

QUESTIONS TO ASK YOUR DOCTOR

- What other medical specialists does my child need to see?
- What foods does my child need to avoid completely?
- Is there a cure for this disorder?

legumes, organ meats, and processed meats contain considerable galactose and must be avoided. Pills that use lactose as a filler must also be avoided. Soy-based and casein hydrolysate-based formulas are recommended for infants with galactosemia.

Treatment of the severe form of galactosemia III with a galactose-restricted diet has been tried, but this disorder is so rare that the long-term effects of this treatment are unknown.

Since most people are unaware that they are carriers of a gene mutation causing galactosemia, the disease is usually detected on a newborn screening test. For couples with a previous child with galactosemia, prenatal diagnosis is available to determine whether a pregnancy is similarly affected. Families who have a child diagnosed with galactosemia can have DNA testing, which would enable other relatives to determine their carrier status. Prospective parents can then use that information to conduct family planning or to prepare for a child with special circumstances. Children born with galactosemia should be put on a special diet right away to reduce the symptoms and complications of the disease.

Prognosis

Early detection in the newborn period is the key to controlling symptoms. Long-term effects in untreated babies include severe intellectual disability, cirrhosis of the liver, and death. About 75% of untreated babies die within the first two weeks of life. On the other hand, with treatment, a significant proportion of people with galactosemia type I can lead nearly normal lives, although speech defects, learning disabilities, and behavioral problems are common. In addition, cataracts due to galactosemia II can be completely prevented by a galactose-free diet.

Galactosialidosis

Definition

Galactosialidosis is a rare inherited metabolic disorder with multiple symptoms that can include skeletal abnormalities, intellectual disability, and progressive neurological degeneration.

Description

Galactosialidosis is a very rare genetic disorder with progressive signs and symptoms that are almost identical to those of neuraminidase deficiency alone, a disorder that is often called sialidosis. These symptoms can include skeletal and facial abnormalities, seizures, vision and hearing loss, cardiac and kidney problems, and intellectual disability. However, as with sialidosis, the severity of the symptoms of galactosialidosis varies greatly.

Galactosialidosis is a member of a large family of disorders called lysosomal storage disorders, each of which is caused by a deficiency in a specific lysosomal protein or

enzyme. Galactosialidosis is caused by the absence or impaired functioning of an enzyme called cathepsin A that affects the functioning of other enzymes and causes various substances to accumulate in lysosomes.

Galactosialidosis is also known as Goldberg syndrome, after M. F. Goldberg and colleagues who first described the disorder in 1971. The disorder is also sometimes called protective protein/cathepsin A (PPCA) deficiency, deficiency of lysosomal protective protein, neuraminidase deficiency with beta-galactosidase deficiency, or deficiency of cathepsin A.

Galactosialidosis is caused by a mutation, or change, in the gene encoding cathepsin A. Cathepsin A forms a very large multi-enzyme complex with three other enzymes: beta-galactosidase, N-acetylgalactosamine-6-sulfate sulfatase (GALNS), and alpha-N-acetylneuraminidase. The latter enzyme is commonly referred to as neuraminidase 1 or sialidase. Whereas sialidosis is caused by a mutation in the gene encoding neuraminidase, a mutation in the gene encoding cathepsin A can affect the activities of all of the enzymes in the complex. However, neuraminidase is the enzyme that is most dependent on cathepsin A. Without functional cathepsin A, there is little or no neuraminidase activity. Although beta-galactosidase activity is reduced, a significant amount of active enzyme remains. Therefore, the symptoms of galactosialidosis are more similar to those of sialidosis than to those of beta-galactosidase deficiency. Mutations in the gene encoding beta-galactosidase can result in disorders known as GM1-gangliosidosis (beta-galactosidosis) or Morquio B disease.

Cathepsin A also forms a complex on the cell surface with neuraminidase 1 and the elastin binding protein produced from the same gene as lysosomal beta-galactosidase. Elastin binding protein plays a role in the formation of elastic fibers in connective tissues.

Galactosialidosis is subdivided into three types, depending on the age of onset: severe, neonatal or early-infantile; milder, late-infantile; and juvenile/adult. The juvenile/adult form is the most common. There also is an atypical form of galactosialidosis. The type and severity of the disorder depends on the specific mutation(s) present in the genes encoding cathepsin A.

Lysosomal storage diseases

Neuraminidase, beta-galactosidase, cathepsin A, and GALNS are all enzymes that function inside lysosomes. Lysosomes are membrane-bound spherical compartments or vesicles within the cytosol (fluid part) of cells. Lysosomes contain more than 50 different enzymes that are responsible for digesting, or hydrolyzing, large molecules and cellular components. These include proteins, polysaccharides (long linear or branched chains of sugars),

and lipids (large, insoluble biomolecules that are usually built from fatty acids). The smaller breakdown products from the lysosome are recycled back to the cytosol.

Galactosialidosis is one of at least 41 genetically distinct lysosomal storage diseases. In these disorders, some of the macromolecules in the lysosome cannot be degraded. Instead, these large molecules or their partial-breakdown products accumulate, and the lysosomes swell to the point that cellular function is disrupted.

Neuraminidase deficiency

Neuraminidase removes sialic acid from the ends of oligosaccharides, which are relatively short chains of sugars. Sialic acid, also known as N-acetylneuraminic acid, is a type of sugar molecule that often is at an end of an oligosaccharide. These oligosaccharides with terminal sialic acid residues may be attached to proteins called glycoproteins.

Neuraminidase deficiency prevents the breakdown of oligosaccharides and glycoproteins that contain sialic acid, and leads to the accumulation and excretion of these substances. It also can lead to the production of abnormal proteins. Following protein synthesis, some lysosomal enzymes reach the lysosome in an inactive form and require further processing for activation. One such processing step is the neuraminidase-catalyzed removal of sialic acid residues from oligosaccharides on enzymes. Thus, under conditions of neuraminidase deficiency, other lysosomal enzymes may not behave properly.

Cathepsin A

Cathepsin A is required for the transport of neuraminidase to the lysosome. Once inside the lysosome, the enzymatic activity of cathepsin A may be involved in the activation of neuraminidase. Furthermore, cathepsin A mediates the association of multiple molecules of neuraminidase and beta-galactosidase, as well as GALNS. In the absence of cathepsin A, all three enzymes are rapidly degraded in the lysosome. Thus, cathepsin A protects and stabilizes these enzyme activities. In the absence of cathepsin A, substrates for these enzymes may accumulate to dangerous levels.

Gangliosides are very complex components of cell membranes. They are made up of a long-chain amino alcohol called sphingosine, a long-chain fatty acid, and a very complex oligosaccharide that contains sialic acid. Lysosomal beta-galactosidase is responsible for hydrolyzing gangliosides.

GALNS catalyzes the first step in the lysosomal breakdown of a special type of sugar called keratan sulfate. Both gangliosides and keratan sulfate may accumulate with galactosialidosis.

In addition to its protective functions, cathepsin A has at least three enzymatic activities of its own, including the ability to cleave (break apart or hydrolyze) other proteins. Some of the neurological abnormalities that develop with galactosialidosis may be due to the loss of this activity, particularly cathepsin A's ability to cleave endothelin-1. This peptide is overabundant and abnormally distributed in the neurons and glial cells of the brain and spinal cord of individuals with galactosialidosis.

Genetic profile

Galactosialidosis is an autosomal recessive disorder that can be caused by any one of a number of different mutations in the gene encoding cathepsin A. This gene is known as *CTSA*. It is sometimes called *PPGP*, for beta-galactosidase protective protein. The disorder is autosomal since the *CTSA* gene is located on chromosome 20, rather than on the X or Y sex chromosomes. The disorder is recessive because it only develops when both genes encoding cathepsin A, one inherited from each parent, are abnormal. However, the two defective genes do not need to carry the same mutations. If the two mutations are identical, the individual is a homozygote. If the two mutations are different, the affected individual is called a compound heterozygote.

CTSA mutations

The type of galactosialidosis and the severity of the symptoms depend on the specific mutations that are present. In general, the higher the level of cathepsin A activity in the lysosomes, the milder the characteristics of galactosialidosis, and the later the onset of disease.

With some mutations in the *CTSA* gene, very little of the cathepsin A precursor protein is produced, and there is no mature cathepsin A in the lysosome. With other mutations, the precursor protein may not be correctly processed into mature protein. Some individuals with severe early-infantile galactosialidosis carry mutations that prevent precursor cathepsin A from being targeted to the lysosome. The lysosomes of these individuals have no cathepsin A.

In contrast, individuals with the late-infantile form of galactosialidosis carry at least one mutant *CTSA* gene whose product can reach the lysosome. However, there may be only a small amount of cathepsin A in the lysosome, the cathepsin A may lack enzymatic activity, the cathepsin A chains may be unable to combine to form the normal two-chained form, or the cathepsin A may be degraded rapidly. Nevertheless, with these mutations, the symptoms of galactosialidosis are mild and progress very slowly with no intellectual disability.

Other identified mutations prevent the cathepsin A molecules from folding properly, or shorten the cathepsin A protein so that it cannot form a complex with the other enzymes.

Compound heterozygotes, with different mutations in their *CTSA* genes, usually have symptoms that are intermediate in severity between those of homozygotes. Occasionally, the symptoms of a compound heterozygote may be milder than those of either homozygote because the two mutant cathepsin A proteins can complement, or compensate, for each other's abnormalities. Genetic testing may be available for mutations in the *CTSA* gene.

Demographics

As an autosomal recessive disorder, galactosialidosis occurs with equal frequency among males and females. Since it requires two defective copies of the *CTSA* gene, one inherited from each parent, it is much more common in the offspring of couples who are related to each other (consanguineous), such as first or second cousins.

Galactosialidosis appears to occur with the highest frequency among Japanese. The juvenile/adult form is particularly common among Japanese, and specific mutations in the *CTSA* gene occur with a high frequency in this population.

Signs and symptoms

Although the features of galactosialidosis vary greatly, they are very similar to those of neuraminidase deficiency (sialidosis). These progressive symptoms include red spots in the eyes known as cherry-red macules. Eventually, the corneas may become cloudy, and cataracts and blindness may develop. Hearing loss is also common with galactosialidosis.

Myoclonus or sudden involuntary muscle contractions may become debilitating and may eventually develop into myoclonic seizures. Tremors and various other neurological conditions may develop. There may be a progressive loss of muscle coordination, called ataxia, and walking and standing can become increasingly difficult.

Small red skin lesions called angiokeratoma are signs of galactosialidosis. Swollen liver and spleen (hepatosplenomegaly) may develop. Cardiac disease can be one of the major consequences of the disorder.

Symptoms of the more severe forms of galactosialidosis include coarse or malformed facial features and a variety of skeletal malformations (dysostosis multiplex), including short stature. Intellectual disability also may be present. Galactosialidosis is one cause of nonimmune hydrops fetalis, the excessive accumulation of fluid in the fetus.

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Beta-galactosidase—An enzyme that forms a complex with cathepsin A.

Dysostosis multiplex—A variety of bone and skeletal malformations.

Fibroblast—A cell that forms connective tissue fibers such as skin.

Ganglioside—A complex membrane lipid made up of a long-chain fatty acid, a long-chain amino alcohol, and an oligosaccharide containing sialic acid.

Glycoprotein—A protein with at least one carbohydrate group.

Heterozygote—Having two different versions of the same gene.

Homozygote—Having two identical copies of a gene or chromosome.

Lysosome—A membrane-enclosed compartment in cells, containing many hydrolytic enzymes; where large molecules and cellular components are broken down.

Myoclonus—Twitching or spasms of a muscle or an interrelated group of muscles.

Oligosaccharide—Several monosaccharide (sugar) groups joined by glycosidic bonds.

Polysaccharide—A linear or branched macromolecule composed of numerous monosaccharide (sugar) units linked by glycosidic bonds.

Recessive—Refers to a genetic trait that is expressed only when present on both members of a pair of genes, one inherited from each parent.

Sialic acid—N-acetylneuraminic acid, a sugar that is often at the end of an oligosaccharide on a glycoprotein.

Sialidosis—An inherited disorder also known as neuraminidase deficiency.

Vacuolation—The formation of multiple vesicles, or vacuoles, within the cytosol of cells.

multiplex. Magnetic resonance imaging (MRI) or computer tomography (CT) scans may be used to determine brain atrophy. An electroencephalogram (EEG) may indicate epileptic activity.

Neuraminidase activity

Typically, neuraminidase deficiency is diagnosed by measuring the activity of the enzyme in cultures of fibroblast cells (connective-tissue cells) that have been grown from cells obtained by a skin biopsy. Neuraminidase activity usually is measured by testing the ability of fibroblast cell preparations to hydrolyze, or cleave, a synthetic compound such as 4-methylumbelliferyl-D-N-acetylneuraminic acid. Hydrolysis by neuraminidase liberates 4-methylumbelliferone, which is a compound with fluorescence that can be measured accurately. The normal range of neuraminidase activity in fibroblasts is 95–653 picomoles per minute per milligram of protein. With galactosialidosis, neuraminidase activity in fibroblasts may be less than 4% of normal.

Beta-galactosidase activity

Beta-galactosidase activity in blood cells is measured in much the same way as neuraminidase activity in fibroblasts. Using the substrate 4-methylumbelliferyl-alpha-D-galactopyranoside, the fluorescence of 4-methylumbelliferone that is liberated through the action of beta-galactosidase is measured.

In severe forms of galactosialidosis, beta-galactosidase activity is less than 15% of normal, and neuraminidase activity is less than 1% of normal. The combination of low beta-galactosidase and low neuraminidase in fibroblasts, with normal levels of other lysosomal enzymes, is diagnostic for galactosialidosis.

Cathepsin A activity

The enzymatic activity of cathepsin A also can be measured in fibroblasts. In the early-infantile form of galactosialidosis, cathepsin A activity may be completely lacking. A small amount of cathepsin A activity (2%–5% of normal) usually is present in the lysosomes of individuals with other forms of galactosialidosis. The highest levels of cathepsin A activity are associated with the least severe and later-onset forms of the disorder. Carriers with a single mutated *CTSA* gene may have only half of the normal level of cathepsin A activity even though they are without symptoms of the disorder.

Histology

Galactosialidosis causes the lysosomes to fill with sialyloligosaccharides and sialylglycopeptides (partially degraded proteins with sialyloligosaccharides still

Diagnosis

Early-infantile onset

Some findings of galactosialidosis, including facial and skeletal abnormalities, may be apparent at birth. Skeletal x-rays may be used to diagnose dysostosis

QUESTIONS TO ASK YOUR DOCTOR

- Why do you believe my child has galactosialidosis?

attached). These swollen lysosomes may form inclusion bodies and give cells a vacuolated appearance that is diagnostic of lysosomal storage disease.

Neuraminidase deficiency may be diagnosed by histological or microscopic examination of a number of different types of cells that may show this cytosolic vacuolation. These cells include the Kupffer cells of the liver, lymphocytes (white blood cells that produce antibodies), bone marrow cells, epithelial skin cells, fibroblasts, and Schwann cells, which form the myelin sheaths of nerve fibers.

Urine tests

Neuraminidase deficiency may be diagnosed by screening urine for the presence of sialyloligosaccharides, using chromatography to separate the components of the urine on the basis of size and charge. In unaffected individuals, sialyloligosaccharides are cleaved by neuraminidase and therefore are present in the urine in only very low amounts. With neuraminidase deficiency, urine levels of sialyloligosaccharides may be three to five times higher than normal.

Sialylglycopeptides can be detected in the urine under conditions of neuraminidase deficiency. In galactosialidosis, keratan sulfate, which accumulates because of the low activity of GALNS, also can be identified in the urine.

Prenatal diagnosis

Galactosialidosis may be diagnosed prenatally. In at-risk fetuses, cultured fetal cells from the amniotic fluid (amniocytes), obtained by amniocentesis or cultured chorionic villi cells, obtained by chorionic villus sampling (CVS) in the early weeks of pregnancy, may be tested for neuraminidase and beta-galactosidase activities. Furthermore, the enzymatic activities of cathepsin A can be measured in amniocytes and chorionic villi. Cathepsin A activity is normally very high in these cells, and low activity is an indication of an affected fetus. However,

since carriers of a single mutated *CTSA* gene do not have symptoms of galactosialidosis, it may be difficult to recognize an at-risk fetus unless there is a family history of the disorder. Genetic testing for mutations in the *CTSA* gene is available from a number of labs in the United States, Canada, and Europe as of 2021.

Treatment and management

At present, there is no treatment for galactosialidosis. Rather, attempts are made to manage individual symptoms. Myoclonic seizures in particular, are very difficult to control.

Prognosis

The prognosis for individuals with this disorder varies greatly depending on the specific genetic mutation, which determines the age of onset and severity of the disease. Individuals with mild forms of galactosialidosis may have nearly normal life expectancies. However, the early-infantile form of galactosialidosis usually results in death shortly after birth.

Gamete donor anonymity

Definition

Gamete donor anonymity refers to the practice of protecting the identities of people who donate male sperm, female oocytes, or embryos as third parties for assisted reproductive technologies (ART), most often in vitro fertilization (IVF). The term *donor* is still used, even though most gamete donors are compensated financially for their donations.

Gamete donor anonymity has become a vexed question in developed countries as of 2021 because of the conflicting perspectives and wishes of gamete donors, gamete recipients, and the offspring born through ART. Of the eight million children born worldwide since the introduction of IVF in 1978, at least two million of these children were born as the result of gamete and embryo donation.

Description

Gamete donor anonymity was standard practice from the earliest experiments with IVF up through the early twenty-first century, when a combination of technological and social changes made donor anonymity difficult to maintain. Although some countries have instituted legislative changes requiring open sperm or egg donation (also called known donation or identity disclosure donation), others continue to allow anonymous gamete donations even while encouraging disclosure among donors, recipients, and the resultant offspring.

History of sperm donation

Maintaining anonymity has always been simpler for sperm donors, because the ejaculation of semen is a natural process that occurs outside the male body, whereas oocyte retrieval involves a surgical procedure—the insertion of a needle through a woman's vagina to her ovaries to remove oocytes through aspiration. In addition, given the fact that some law codes held the biological father of a child responsible for financial support, both sperm donors and the physicians who assisted infertile male patients had both social and legal reasons to maintain donor anonymity.

The earliest-known successful case of a healthy full-term pregnancy resulting from donor insemination took place in Philadelphia in 1884. Dr. William Pancoast, a well-known local physician, was approached by the wife of a wealthy merchant who was concerned that she was sterile. Pancoast determined that it was the husband whose low sperm count—the result of a severe case of gonorrhea—was responsible for the wife's inability to

conceive. Pancoast therefore called the wife back to his office for another “examination,” during which he gave her chloroform, inserted fresh semen obtained from one of the six medical students invited to observe the procedure, and packed the wife's cervix with gauze. Nine months later, the woman gave birth to a healthy baby boy. The full story did not come out until 1909, when one of the medical students present at the 1884 procedure wrote a letter to a medical journal describing what had taken place. He did inform the son, then a twenty-five-year-old businessman, of the circumstances of his conception before publishing the letter.

Prior to the 1980s, sperm donations were typically obtained privately by physicians from their friends or colleagues for use in either intracervical insemination (ICI), in which raw semen is inserted deep into the woman's vagina as close to the cervix as possible; or intrauterine

insemination (IUI), in which washed sperm are inserted directly into the uterus through a catheter. Anonymity was taken for granted by both donors and recipients. After IVF was introduced in 1978, growing interest in ART led to a shortage of donated sperm. In the 1980s, medical students and college undergraduates were recruited to donate sperm, paid for their donations, and promised anonymity; however, semen samples were rarely tested for sexually transmitted diseases (STIs). This policy changed in 1988 in response to the AIDS crisis, when the Centers for Disease Control and Prevention (CDC) required sperm donors to be tested for HIV antibodies at the time of donation, their semen to be frozen, and retested six months later before the gametes could be used.

Some countries have instituted limits on the number of offspring that a sperm donor's donations may produce. The reason for limitation is to lower the risk of accidental incest; that is, sexual activity or marriage between persons unaware of a close familial relationship between them. While limitations imposed by law on sperm donation are common worldwide, they are voluntary in the United States and Japan.

History of egg donation

Egg donation is a much more complicated process; it was not considered feasible until 1983, when the first successful oocyte donation took place in Australia. By 1987, 17 fertility centers in the United States offered oocyte donation, a number that increased to over 400 centers by 2005. As with sperm donors, oocyte donors had to be recruited when the demand for their gametes outran the supply. The first oocyte donors were typically women undergoing IVF who were willing to donate their extra oocytes, or women who were friends or relatives of women seeking an oocyte donor. The next group of donors included married women under age 35 who had had all the children they wanted. Physicians then began to recruit college students, on the grounds that oocytes from younger women have a better chance of producing a viable pregnancy, and because college women are presumably of above-average intelligence.

Remuneration for oocyte donation is much higher than for sperm donation because of the inconvenience and health risks involved. An oocyte donor must receive hormonal stimulation timed to coincide with the stimulation given to the recipient; she must then undergo an intrusive procedure in a hospital or fertility clinic in order to retrieve the mature oocytes. Health risks include infection; hyperstimulation of the ovaries; unintentional pregnancy; and reduced fertility in later life. Because of these physical risks and possible psychological complications from the procedure, oocyte donors are paid on

average between \$8,000 and \$10,000 per donation cycle as of 2021, while donors with demonstrated superior intelligence or athletic ability may be offered as much as \$50,000. By contrast, sperm donors are paid an average of \$125 per approved sample.

Technological changes

The contrast between the relative simplicity of sperm donation and the greater complexity of oocyte donation, as well as the different timelines of these two types of gamete donation, reflects the role of medical technology in making gamete donation increasingly widespread and thereby calling donor anonymity into question. There are three changes in particular that are relevant in this context: the rise of the Internet and social media; advances in DNA identification and analysis; and the popularity of direct-to-consumer genetic testing.

The Internet and social media made it possible for large numbers of people worldwide to share information and opinions with thousands and potentially millions of online viewers. This ease of communication led many participants to share personal and family secrets that would have been previously kept private, and some were encouraged to disclose more and more information about their lives. One common issue was the matter of adoption; younger Internet users, particularly the so-called Millennials and Generation Z, have little difficulty in turning to the Web to locate information about their biological parents if they know themselves to be adoptees.

The Internet has also made it possible for people to learn about advances in DNA detection and analysis, and apply that information to their own situation. Since 1985, when DNA was first used to solve a homicide case in the United Kingdom, forensic laboratories have been able to use smaller and smaller samples of DNA from body fluids and skin cells to identify criminals, and this same improvement in technology was put to use for the general public in the early direct-to-consumer DNA test kits.

The first DTC genetic tests were marketed within a few years after the completion of the Human Genome Project in 2003. These first tests were expensive, costing about \$1,000, but improvements in technology led to the price dropping to as low as \$59 by 2018. As the price of DTC testing fell, its popularity increased, as did its advertising in the mass media. The accumulation of data from DTC testing by such services as GEDmatch has made it increasingly easy for adoptees searching for their biological parents to track down their relatives. Some geneticists estimate that so many DTC tests have been completed in the United States that even people who have not taken such a test are likely to be related genetically to

someone who has—making gamete donor anonymity all but impossible.

Still another technological development has complicated gamete donor anonymity, namely facial recognition software. The Center for Human Reproduction (CHR) in New York City reported a case in 2018 in which a third party recognized one of the center's oocyte donors by comparing the donor's anonymous photograph on the center's website with the same photograph on the donor's social media account.

Social changes

Changes in technology have intersected with changes in social attitudes regarding family structure, sexism, children's rights, and patients' rights. One longstanding reason for gamete donor anonymity was to protect the traditional nuclear family, understood as a husband and wife and their legitimate offspring. This protection was based on three premises that are no longer generally accepted: the notion that doctors always know what is best for patients; that men have the right to decide what women are allowed to know; and that the wishes of adults for secrecy are privileged over the interests of children for disclosure. The Pancoast incident is a good historical example of this paternalism. The physician did not inform the husband of the artificial insemination until after the baby's birth; both men agreed to keep the wife in the dark about it; and the son was not informed until he was 25, and then only because one of the former medical students did so as a courtesy before his letter about the incident was published.

Another motivation for sperm donor anonymity in particular came from the eugenics movement of the 1920s and 1930s. Many eugenicists believed that genetically superior men had an obligation to the species to father as many children as possible, even in violation of conventional morality. One proponent of this view was Charles Lindbergh, the famous aviator. In the mid-1950s, he took advantage of frequent business trips to Europe to father seven children by three different women in Germany, even though he had already had six children by his American wife, Anne.

Social changes that have come about since the 1970s include greater acceptance of nontraditional households, including same-sex couples, single-parent households, and families consisting of three or more unmarried people (sometimes called polyamory). A majority of gamete donors in developed countries have no objection to donating sperm or oocytes to nontraditional families. However, the greater instability of these families and the high rate of divorce and remarriage among heterosexual couples could increase the likelihood that the offspring

may have questions about their genetic identity when they become adults. On the one hand, an ever larger proportion of adolescents and young adults have grown up in households with a shifting population of parents, grandparents, step-parents, and parents' sexual partners, and have adapted as well as they could to the older adults' actions. On the other hand, these same young people are often strongly motivated to search for their biological parents and/or half-siblings in order to resolve their own identity issues.

Legislation regarding donor anonymity

Countries differ in regard to the legality of gamete donor anonymity. Some countries, such as the United Kingdom, Australia, New Zealand, Austria, Germany, Switzerland, Sweden, Norway, and the Netherlands, require gamete donors to make their identifying information available to the resultant offspring when the children reach the age of 18; one result of this legislation has been a measurable drop in the number of men willing to donate sperm. Another result is an increase in fertility tourism—in this context, people traveling from a country where gamete donors are legally identifiable to other countries where donor anonymity is still allowed.

The United States is an outlier in regard to donor anonymity; there is no federal law requiring open identification of gamete donors as of 2021, and private sperm and oocyte donation is still practiced. Although such professional organizations as the American Society for Reproductive Medicine (ASRM) strongly encourage disclosure, they continue to respect the wishes of some gamete donors to remain anonymous.

A document published by the ethics committee of the ASRM in 2018 stated, “The . . . Committee finds that disclosure to offspring about the fact of donor conception and, if available, characteristics of the donor(s), may serve the offspring's best interests. The Committee also recognizes that the decision is a highly personal one about which the parties may have differing values.” The ASRM also recommends psychological counseling and informed consent about disclosure and information sharing for both gamete donors and recipients, as well as advising all parties to keep in mind that later changes in the law may affect any nondisclosure agreements made.

Regulation of sperm banks and fertility clinics in the United States

In the United States, sperm banks and clinics offering donated semen are required by law to register with the Food and Drug Administration (FDA), which can perform unannounced on-site inspections. The FDA is primarily concerned, however, with the risk of infectious disease

KEY TERMS

Accidental incest—Sexual activity or marriage between persons who are unaware of a close familial relationship between them.

Assisted reproductive technology (ART)—A collective term for a group of procedures done to address problems with fertility. ART includes such techniques as in vitro fertilization, cryopreservation of donated gametes or embryos, and pre-implantation genetic diagnosis.

Carrier—In genetics, a person who has a genetic mutation associated with a disease and is capable of passing it on. A carrier may or may not display the symptoms of the disease.

Ethics—The branch of philosophy dealing with questions of good and evil, and with moral duties and obligations in human society.

Eugenics—A set of beliefs and practices intended to improve the genetic quality of a country's human population, either by limiting the reproduction of people considered unfit or by encouraging the reproduction of healthier, more intelligent, and more attractive people.

Fertility fraud—A recently coined term for physicians' use of their own sperm in assisted reproductive techniques.

Fertility tourism—The practice of traveling to another jurisdiction or country for fertility treatments unavailable or illegal in one's own country.

Forensic—Pertaining to the use of science or medicine in the investigation and establishment of evidence in a court of law.

Gamete—A sex cell (sperm or ovum) containing the haploid number of chromosomes and capable of

fusing with a gamete of the opposite sex to form a zygote.

Haploid—Referring to cells that have only one chromosome of each type, and therefore have only one complete set of genes.

In vitro fertilization (IVF)—A form of assisted reproduction technology in which a human ovum (egg) is combined with sperm outside the body in a laboratory container ("in vitro" means "in glass").

Informed consent—The process of obtaining permission from a person before conducting a health care procedure on a person, enrolling a person in a clinical trial, or disclosing that person's private information.

Oocyte (pronounced OH-uh-site)—A diploid cell in females from which an egg or ovum develops by meiosis.

Pre-implantation genetic testing (PGT)—A screening test performed on embryos created by IVF to analyze the genetics of each embryo prior to transfer into the intended mother's uterus.

Surrogacy—The practice in which a woman, called a surrogate mother, carries a pregnancy to term for another person or persons who cannot have children, who will become the legal parent(s) of the child after birth. Surrogacy may or may not involve a legal contract.

Third-party reproduction—Any instance of human reproduction in which DNA or gestation is provided by a third-party donor other than the parent(s) who will rear the resulting child. It is also called donor-assisted reproduction.

transmitted through semen; it does not deal with screening and testing for genetic disorders. The FDA regulates oocyte as well as sperm donation under the general heading of human tissue and tissue products. Some states, including New York and California, regulate sperm banks, but most do not.

Sperm banks and fertility clinics offering oocyte donation may register with the American Association of Tissue Banks (AATB), an organization established in 1977. Registration with the AATB is voluntary as of 2021, however; it is not required by either federal or state law.

The CDC collects data about ART from over 440 fertility clinics in the United States as of 2021. Its system

is called the National Assisted Reproductive Technology Surveillance System or NASS. NASS is, however, intended to measure the success and outcomes of assisted reproductive technologies carried out in these clinics. While patient data include demographic characteristics and medical histories, DNA profiles are not included, and the CDC does not have an official position on gamete donor anonymity.

Fertility fraud cases

One direct result of the boom in DTC genetic testing has been the uncovering of what is termed fertility fraud—that is, physicians' use of their own semen to inseminate

- What is your opinion of gamete donor anonymity?
- Have any of your patients used the results of DTC genetic testing to look for their biological parents or previously unknown relatives?
- Have any of your patients been affected by fertility fraud?

patients who thought they were receiving either their husbands' sperm or that of an anonymous donor. Beginning around 2014, both recipients of donated sperm and their now-grown offspring discovered through DTC testing that the donated sperm had been provided by the recipients' doctors. As of 2021, cases of fertility fraud have led to lawsuits not only in the United States (in Indiana, California, Texas, Virginia, Idaho, and Vermont) but also in Canada and the Netherlands. One Indianapolis physician is known to have fathered over 50 children, while the Canadian physician whose medical license was revoked in 2014 fathered at least 16 children.

According to legal professionals, however, it is difficult to define the precise crime that these doctors committed at the time that sperm donation was considered confidential. When a Virginia physician was taken to court in 1992 for using his own sperm to impregnate his patients, prosecutors discovered there was no law on the books prohibiting doctors from administering their own sperm to unwitting patients; they had to prosecute the doctor on 52 counts of perjury and fraud. A new law passed in Indiana in 2019 makes fertility fraud a felony and allows families affected by such fraud before 2019 to bring a civil suit in court. Texas passed similar legislation criminalizing fertility fraud in 2019, and Florida and Colorado followed in 2020.

Gastric cancer

Definition

Gastric cancer (also known as stomach cancer) is a disease in which the cells forming the inner lining of the stomach become abnormal and start to divide uncontrollably, forming a mass or a tumor.

Description

The stomach is a J-shaped organ that lies in the abdomen, on the left side. The esophagus (or the food pipe) carries the food from the mouth to the stomach. The stomach produces many digestive juices and acids that mix with the food and aid in the process of digestion. The stomach is divided into five sections. The first three are together referred to as the proximal stomach and produce acids and digestive juices, such as pepsin. The fourth section of the stomach is where the food is mixed with the gastric juices. The fifth section of the stomach

acts as a valve and controls the emptying of the stomach contents into the small intestine. The fourth and the fifth sections together are referred to as the distal stomach. Cancer can develop in any of the five sections of the stomach. The symptoms and the outcomes of the disease may vary depending on the location of the cancer.

In many cases, the cause of the gastric cancer is unknown. Several environmental factors have been linked to gastric cancer. Consuming large amounts of smoked, salted, or pickled foods has been linked to increased gastric cancer risk. Nitrates and nitrites, chemicals found in some foods such as cured meats may be linked to gastric cancer as well.

Infection by the *Helicobacter pylori* (*H. pylori*) bacterium has been found more often in people with gastric cancer. *H. pylori* can cause irritation of the stomach lining (chronic atrophic gastritis), which may lead to precancerous changes of the stomach cells.

People who have had previous stomach surgery for ulcers or other conditions may have a higher likelihood of developing gastric cancers, although this is not certain. Another risk factor is developing polyps, benign growths in the lining of the stomach. Although polyps are not cancerous, some may have the potential to turn cancerous.

People with blood relatives who have been diagnosed with gastric cancer have an increased risk of developing the disease. In addition, people who have inherited disorders such as hereditary diffuse gastric cancer (HDGC), familial adenomatous polyposis (FAP), and Lynch syndrome have an increased risk for gastric cancer. For unknown reasons, gastric cancers occur more frequently in people with the blood group A.

Genetic profile

Although environmental or health factors may explain frequent occurrences of gastric cancer in families, it is known that inherited risk factors also exist. Some studies show close relatives having an increased risk of gastric cancer two to three times that of the general population. The primary gene currently associated with gastric cancer is the *CDH1* gene, and other possible gene mutations include mutations from the *MAP3K6* gene.

Familial cancer syndromes are hereditary conditions in which specific types of cancer, and perhaps other features, are consistently occurring in affected individuals. HDGC, FAP, and hereditary nonpolyposis colon cancer (HNPCC) are familial cancer syndromes that increase the risk of colon cancer. HNPCC is a hereditary colon cancer with an autosomal dominant type of inheritance. It has a possible underlying mutation in one or more of

Gastric cancer: pedigree analysis chart (Gale)

the following genes: *MSH2*, *MLH1*, *MSH6*, *PMS1*, and/or *PMS2*.

FAP is due to changes in the *APC* gene, although a reported 25%–30% of cases are *de novo* mutations, which means they are not related to family history. Individuals with FAP typically have more than 100 polyps (mushroom-like growths) in the digestive system, as well as other effects. Polyps are noncancerous growths that have the potential to become cancerous if not removed. At least one study estimated that the risk of gastric cancer was seven times greater for individuals with FAP than for the general population.

The number of polyps present is an important distinction between FAP and HNPCC. Polyps do not form at such a high rate in HNPCC, but individuals with this condition are still at increased risk of colon, gastric, and other cancers. At least five genes are known to cause HNPCC, but alterations in the *hMSH2* or *hMLH1* genes have been found in the majority of HNPCC families.

Other inherited conditions such as Peutz-Jeghers, Cowden, Li-Fraumeni, and other syndromes have been associated with gastric cancer. All of these syndromes have distinct features beyond gastric cancer that aid in identifying the specific syndrome. The inheritance pattern for most of these syndromes is dominant, meaning that

only one copy of the gene needs to be inherited for the syndrome to be present.

Current standards for defining hereditary gastric cancer not due to known genetic conditions are often applied. In areas with low rates of gastric cancer, hereditary gastric cancer has been defined according to the International Gastric Cancer Linkage Consortium as (1) families with two or more cases of gastric cancer in first- or second-degree relatives (siblings, parents, children, grandparents, nieces/nephews, or aunts/uncles) with at least one case diagnosed before age 50; or (2) three or more cases at any age. In countries with higher rates of gastric cancer, such as Japan, the suggested criteria are (1) at least three affected first-degree relatives (sibling, children, or parents) with one being the first-degree relative of the other two; (2) at least two affected generations (without a break); and (3) at least one cancer occurrence before age 50.

Inherited changes in the *E-Cadherin/CDH1* gene first were reported in three families of native New Zealander (Maori) descent with gastric cancer and later were found in families of other ancestry. The *E-Cadherin/CDH1* gene, which plays a role in cell to cell connection, is located on chromosome 16 at 16q22. The percentage of hereditary gastric cancer that is due to *E-Cadherin/CDH1* gene alterations is uncertain. In

Gastric Cancer

Autosomal Dominant / Familial

Gastric cancer: pedigree analysis chart (Gale)

summary, most gastric cancer is due to environmental or other non-genetic causes. A small portion of cancer of the stomach, about 8%, is due to inherited factors, one of which is *E-Cadherin/CDH1* gene alterations.

Demographics

Gastric cancer is the fourth most common cancer throughout the world, with an estimated 900,000 cases per year. It is one of the leading causes of cancer deaths in many areas of the world, most notably Japan and Korea, but the number of new gastric cancer cases is decreasing in some areas, especially in developed countries. As of 2015, death due to gastric cancer had been reported in over 723,000 individuals, and of that an estimated 1%–3% was due to a hereditary predisposition. In the United States, the use of refrigerated foods and increased consumption of fresh fruits and vegetables instead of preserved foods may be a reason for the decline in gastric cancer. Early screening, especially in those with a family history, may also be a reason behind a recent decline.

Signs and symptoms

Gastric cancer can be difficult to detect at early stages since symptoms are uncommon and frequently unspecific. The following can be symptoms of gastric

cancer: poor appetite or weight loss; fullness even after a small meal; abdominal pain; heartburn; belching; indigestion or nausea; vomiting, with or without blood; welling or problems with the abdomen; anemia; or blood on stool (feces) examination. Signs and symptoms of gastric cancer typically do not occur until later stages, making the prognosis poor due to a late diagnosis.

Diagnosis

In addition to a physical examination and fecal occult blood testing (checking for blood in the stool), special procedures are done to evaluate the digestive system including the esophagus, stomach, and upper intestine. Procedures used to diagnose gastric cancer include barium upper gastrointestinal (GI) x-rays, upper endoscopy, and endoscopic ultrasound. Genetic testing can also be used to determine an individual's predisposition to gastric cancer.

Upper GI x-rays

The first step in evaluation for gastric cancer may be x-ray studies of the esophagus, stomach, and upper intestine. This type of study requires drinking a solution with barium to coat the stomach and other structures for easier viewing. Air is sometimes pumped into the stomach to help identify early tumors.

KEY TERMS

Adenocarcinoma—A type of cancer that originates in glandular tissue, has glandular characteristics, or both.

Barium—A chemical put into a solution and swallowed to help with outlining the gastrointestinal system during an x-ray study.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Cancer—A disease caused by uncontrolled growth of the body's cells.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Chronic atrophic gastritis—Irritation and breakdown of the stomach wall over a period of time.

Dominant inheritance—A type of genetic inheritance pattern that results in one form of a gene being dominant over other forms. Therefore, the dominant allele can express itself and cause disease even if only one copy is present.

Duodenum—Portion of the small intestine nearest the stomach; the first of three parts of the small intestine.

E-Cadherin/CDH1—A gene involved in cell-to-cell connection. Alterations in this gene have been found in several families with increased rates of gastric cancer.

Endoscope—A slender, tubular optical instrument used as a viewing system for examining an inner part of the body. With an attached instrument, the endoscope can be used for biopsy or surgery.

Esophagus—The part of the digestive tract that connects the mouth and stomach; the food pipe.

Familial adenomatous polyposis (FAP)—Inherited syndrome causing large numbers of polyps and increased risk of colon cancer and other cancers.

Familial gastric cancer—Gastric cancer that occurs at a higher rate in some families.

Fecal occult blood test—Study of stool (feces) to identify loss of blood in the gastrointestinal system.

Gastric—Associated with the stomach.

Gastrointestinal (GI) system—Body system involved in digestion, the breaking down and use of food.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Genetic counselor—A health professional with advanced training in genetics and psychology who educates people about genetic conditions and testing.

Helicobacter pylori (H. pylori)—Bacterium that infects humans and may be associated with an increased risk of gastric cancer.

Hereditary non-polyposis colon cancer (HNPCC)—A genetic syndrome causing increased cancer risks, most notably colon cancer. Also called Lynch syndrome.

Li-Fraumeni syndrome—Inherited syndrome known to cause increased risk of different cancers, most notably sarcomas.

Lymph node—A bean-sized mass of tissue that is part of the immune system and is found in different areas of the body.

Nitrates/nitrites—Chemical compounds found in certain foods and water that, when consumed, may increase the risk of gastric cancer.

Pernicious anemia—A blood condition with decreased numbers of red blood cells related to poor vitamin B12 absorption.

Peutz-Jeghers syndrome (PJS)—Inherited syndrome causing polyps of the digestive tract and spots on the mouth as well as increased risk of cancer.

Polyp—A mass of tissue bulging out from the normal surface of a mucous membrane.

Radiation—High-energy rays used in cancer treatment to kill or shrink cancer cells.

Staging—A method of describing the degree and location of cancer.

Stomach—A muscular hollow organ that secretes gastric acid and digestive enzymes, and continues the process of digestion begun with chewing.

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

X-ray—An image of the body made by the passing of radiation through the body.

Upper endoscopy

Endoscopy allows a diagnosis in about 95% of cases. In upper endoscopy, a small tube called an endoscope is placed down the throat so that the esophagus, stomach, and upper small intestine can be viewed. If a suspicious area is seen, a small sample of tissue, a biopsy, is taken. The tissue from these samples can be examined for evidence of cancer.

Endoscopic ultrasound

Endoscopic ultrasound allows several layers to be seen, so it is useful in determining where cancer may have spread. With this test, an endoscope is placed into the stomach and sound waves are emitted. A machine analyzes the sound waves to detect differences in the tissues in order to identify tumors.

Genetic testing

If a certain genetic syndrome such as HDGC, FAP, or HNPCC is suspected, genetic testing may be available either through a clinical laboratory or through a research study. Testing for *E-cadherin/CDH1* gene alterations is mainly available through research studies. Once an *E-cadherin/CDH1* gene change is identified through research, the results can be confirmed through a certified laboratory.

When a gene change is identified, genetic testing may be available for other family members. For most genetic tests, it is helpful to test the affected individual first, since he or she is most likely to have a gene change. Genetic testing is usually recommended for consenting adults; however, for syndromes in which gastric cancer is a common feature, testing of children may be reasonable for possible prevention of health problems.

The detection rate and usefulness of genetic testing depends on the genetic syndrome. If genetic testing is under consideration, a detailed discussion with a knowledgeable physician, genetic counselor, or other practitioner is helpful in understanding the advantages and disadvantages of the genetic test. It is also important to realize that testing positive for the *E-cadherin/CDH1* gene does not necessarily mean that the individual will be affected with cancer. However, he or she may have an increased risk compared to an individual without the gene.

Treatment and management

Regular mass screening for gastric cancer has not been found useful in areas such as the United States, where gastric cancer is less common. When gastric cancer is diagnosed in the United States, it is usually discovered at later and less curable stages. However, individuals

with an increased risk of gastric cancer, including those with a known genetic syndrome or with a family history of the disease, may consider regular screening before the development of cancer. If a known hereditary cancer syndrome is suspected, screening should follow the generally accepted guidelines for these conditions.

The current standard of care for the treatment and management of gastric cancer utilizes upper endoscopy and biopsy in families with hereditary gastric cancer, including screening every 6 to 12 months for individuals with known *E-cadherin* gene alterations, if no other treatment has been done. Some individuals with a known hereditary gastric cancer risk have surgery to remove the stomach prior to development of any gastric cancer, but the effectiveness of this prevention strategy is uncertain. Several other less drastic prevention measures have been considered, including changes in diet, use of vitamins, and antibiotic treatment of *H. pylori*. The American Cancer Society recommends limiting use of alcohol and tobacco. Genetic testing for *CDH1* in immediate family members is also a widely used screening method when hereditary gastric cancer has been diagnosed.

Treatment of gastric cancer in nearly all cases involves some surgery. The amount of the stomach or surrounding organs that is removed depends on the size and location of the cancer. Sometimes surgery is performed to try to remove all of the cancer in hopes of a cure, while other times surgery is done to relieve symptoms. Possible side effects of stomach surgery include leaking, bleeding, changes in diet, vitamin deficiencies, and other complications.

Chemotherapy involves administering anticancer drugs either intravenously (through a vein in the arm) or orally (in the form of pills). This can either be used as the primary mode of treatment or after surgery to destroy any cancerous cells that may have migrated to distant sites. Side effects (usually temporary) of chemotherapy may include low blood counts, hair loss, vomiting, and other symptoms.

Radiation therapy is often used after surgery to destroy the cancer cells that may not have been completely removed during surgery. Generally, to treat gastric cancer external beam radiation therapy is used. In this procedure, high-energy rays from a machine that is outside of the body are concentrated on the area of the tumor. In the advanced stages of gastric cancer, radiation therapy is used to ease symptoms such as pain and bleeding.

Prognosis

Staging is a method of describing cancer development. There are five stages in gastric cancer, with stage 0 being the earliest cancer that has not spread while stage

QUESTIONS TO ASK YOUR DOCTOR

- What stage of cancer am I in and what is my prognosis?
- Should my siblings and children be screened for cancer earlier in life now that I have been diagnosed?
- What are my treatment options?

IV includes cancer that has spread to other organs. Expected survival rate can be roughly estimated based on the stage of cancer at the time of diagnosis.

The prognosis for patients with early-stage cancer depends on the location of the cancer. When cancer is in the proximal part of the stomach, only 10%–15% of people survive five years or more, even if they have been diagnosed with early-stage cancer. For cancer that is in the distal part of the stomach, if it is detected at an early stage, the outlook is somewhat better. About 50% of people survive for at least five years or more after initial diagnosis. However, only 20% of the patients are diagnosed at an early stage. Chance of survival depends on many factors, and it is difficult to predict survival for a particular individual.

Gastroschisis

Definition

Gastroschisis, which literally means "split abdomen," is a hernia (open fissure) in the muscle and skin of the abdominal wall that allows the contents of the abdominal cavity to be exposed to the outside of the body. The opening is usually 2–5 in. (5–12.7 cm) long and located in the median plane of the abdomen to the right of the umbilical cord.

Gastroschisis appears during the fetal period and causes the fetal intestines to be exposed to the amniotic fluid with no covering sac. Because amniotic fluid contains the urine of the fetus, this exposure may irritate the fetal intestines, causing swelling and shortening during development. As fetal development progresses, the opening becomes smaller relative to the size of the intestines. Consequently, the bowel may either become strangulated or malrotated. After the infant is born, the intestines are placed back inside the abdominal cavity and the opening is closed surgically. The intestines may still pose long-term functional problems because of the previous irritation and formation of adhesions.

Description

Gastroschisis is caused by a defect in the normal fetal developmental pattern. In fetal development, the midgut (intestines) loops out of the abdominal cavity in a normal process known as physiological umbilical herniation. This process begins in the sixth week of fetal development because there is not enough room in the abdominal cavity for the growing liver, kidneys, and intestines. By the tenth week of fetal development, the liver and kidneys have decreased in size and the abdominal cavity has grown. In a normal fetus, the intestines return to the abdominal cavity at this time, and the abdominal wall forms around them. In a fetus with gastroschisis, the return of the intestine to the abdominal cavity fails to occur. The pancreas, stomach, liver, spleen, bladder, uterus, ovaries, or fallopian tubes are rarely also herniated. The cause of the failure of the intestines to return

to the abdominal cavity is unknown. The attachment of the umbilical cord is normal.

Genetic profile

The cause of gastroschisis is unknown; no definite genetic association has been determined. Chromosomal abnormalities are rarely associated with gastroschisis, and familial occurrence is exceptionally rare. Most genetic centers do not recommend the testing of infants with isolated gastroschisis. The familial cases that have been reported include occurrence in twins. Gastroschisis is not usually seen in association with other types of birth defects. Deformations of the fetal urinary tract can develop because of gastroschisis. These do not represent separate malformations, and genetic testing is not indicated.

A genetically associated issue that may arise is the misdiagnosis of gastroschisis for the distinct condition known as omphalocele. This misdiagnosis occurs in 5% of patients with omphalocele, and has serious implications because omphalocele is often associated with chromosomal abnormalities and additional non-gastrointestinal malformations.

Demographics

Gastroschisis is not a common birth defect. It occurs in approximately 2–6 infants per 10,000 live births in the United States and internationally. Most cases of gastroschisis are sporadic with no familial association. Abnormalities of the intestines as a direct consequence of gastroschisis are seen in 5% of patients. Gastroschisis occurs slightly more often in males than in females. Young maternal age, maternal drug usage, and origination from a socially or economically disadvantaged background all increase the risk of gastroschisis. Very low maternal weight is associated with three times increased risk for gastroschisis. High maternal intake of nitrosamines found in preserved meat and beer doubles the risk of gastroschisis. High maternal weight reduces risk. A low maternal intake of chemicals called carotenoids found in many fruit and vegetables or glutathione from animal protein causes three to four times increased risk for gastroschisis. Carotenoids and glutathione are antioxidants that have a protective effect on the fetus and decrease oxygen stress or oxygen deprivation. Any factor that reduces blood flow to the fetus, thereby causing oxygen stress, can be a factor in the development of gastroschisis. Maternal intake of aspirin or ibuprofen (Advil) causes four to five times increased risk for gastroschisis. Both medications are inhibitors of the cyclooxygenase enzyme and influence blood flow to the fetus. Acetaminophen (Tylenol) has no demonstrated association with gastroschisis. Decongestants, especially pseudoephedrine and phenylpropanolamine, more than double the risk because they cause constriction of blood vessels and decrease blood flow to the fetus. Illness and fever have no association with the development of gastroschisis.

Signs and symptoms

A mother carrying a fetus with gastroschisis will not experience any unusual signs or symptoms in early pregnancy. Gastroschisis may be suspected when maternal serum screening, which is typically performed at 15–20 weeks of gestation, reveals an elevated alpha-fetoprotein level (AFP). Gastroschisis is an open defect in the fetal abdominal wall that allows the leakage of AFP from the fetal tissues into the amniotic fluid. The increased amount of amniotic fluid AFP is absorbed into the maternal circulation and can be easily measured in a maternal serum screening test. An elevated AFP level detected in maternal serum is not indicative of gastroschisis specifically, but this does alert the obstetrician that a detailed ultrasound of the fetus is indicated. An elevated maternal serum AFP level is present in approximately 75%–80% of cases of gastroschisis. Gastroschisis may also be incidentally detected in the second trimester during routine ultrasonography.

KEY TERMS

Amniocentesis—A transabdominal puncture of the amniotic sac to remove amniotic fluid for chemical analysis.

Computerized axial tomography (CAT) scan—A noninvasive technique to show computerized images of a structure in the body.

Exomphalos—An umbilical protrusion or hernia; it is also called omphalocele.

Ultrasonogram—The image produced by the use of inaudible sound of high frequency called ultrasound to photograph a tissue, organ, or infant.

Diagnosis

Ultrasonogram is the primary method of diagnosis for gastroschisis because it is noninvasive, rapid, and allows for real-time fetal monitoring. Gastroschisis is often diagnosed before 20 weeks of gestation by an ultrasonogram that may show some or all of the following: loops of fetal intestines floating exposed to amniotic fluid with or without other organs, signs of intestinal obstruction, or a defect in the middle of the abdominal wall to the right of a normal umbilical cord.

With a transvaginal sonogram, the diagnosis has been made as early as 12 weeks of gestation. The diagnosis may be made difficult by flexed fetal limbs. The detection rate in the United States is approximately 75% with the use of ultrasonogram. Frequent ultrasonograms may be necessary to monitor potential injury to the fetal intestines as the pregnancy progresses. A blood clot around the umbilicus as a result of a traumatic amniocentesis or premature detachment of the placenta may mimic gastroschisis on an ultrasonogram.

Once the infant is born and has received corrective surgery, radiographs and bowel contrast studies may be necessary to diagnose intestinal complications. While these procedures are noninvasive, they expose the infant to a certain level of radiation. A computed axial tomography (CAT) scan is not considered a medically suitable method by which to diagnose gastroschisis. Magnetic resonance imaging (MRI) is not usually used for diagnosis due to high expense and limited availability.

Treatment and management

In cases of gastroschisis, the infant is usually delivered in a hospital with a neonatal intensive care unit. If the infant's other organs are mature enough, the child is often delivered at 36 weeks, often using a cesarean

section. At birth, infants with gastroschisis die without immediate corrective surgery and intensive hospital care. The infant is given intravenous fluids, and the intact intestinal contents are temporarily placed in a surgical plastic clinging film attached to the infant's stomach. The plastic film helps to prevent infection, heat loss, and dehydration.

If the fissure and intestinal spillage is small to medium, the intestines are reinserted into the abdominal cavity and the fissure is surgically closed within 12–24 hours after birth. If the fissure is large or complicated, then the procedure may occur in stages over several days. A silastic bag (silicone plastic called a silo) is used to gradually return the intestines to the abdominal cavity at each stage. Finally the silo is removed and the skin is surgically closed.

Approximately 48% of infants with gastroschisis are small for gestational age. During the recovery period, the infants receive nutrition and fluids intravenously. Once the intestines are able to receive food, infants may begin breast- or bottle-feeding. Normal feedings usually begin by the fourth week from delivery date. However, some infants with gastroschisis have associated complications that require months of intravenous feeding. Infants are discharged from the hospital once they are attaining sufficient weight gain and are followed closely over several months.

Prognosis

The overall prognosis for an infant with gastroschisis without extensive complications is very good. Most deaths occur as a result of premature delivery, infection, and bowel necrosis. The clinical outcome is not correlated with the size of the hernia as estimated using ultrasonography or with the known time of exposure to amniotic fluid. Although the survival rate is high, the postoperative hospitalization is often lengthy with complications. If the intestines sustained damage from exposure to amniotic fluid or from twisting, then the prognosis is of poorer quality. Complications that negatively influence prognosis include intestinal damage, prematurity, fetal growth restriction, and shortening of the gut secondary to irritation. Gastroschisis diagnosed prenatally may resolve in utero, causing the death of portions of the intestines. This may result in a condition known as chronic short gut syndrome with a poor prognosis, including problems with diarrhea, slow weight gain, vitamin or mineral deficiencies, and increased mortality. Spontaneous resolution of gastroschisis and closure of the abdominal hernia have been reported. Gastroschisis may also cause deformations of the fetal urinary tract, resulting in a poor prognosis.

Gaucher disease

Definition

Gaucher (pronounced go-SHAY) disease is a rare genetic metabolic disorder that results in accumulation of fatty molecules called cerebrosides. It can have serious effects on many body organs, including the liver, spleen, bones, and central nervous system.

Description

Gaucher disease was first described by the French physician Philippe Gaucher in 1882. It is the most common of a class of over 50 diseases called lysosomal storage diseases, each of which is characterized by the accumulation of a different chemical substance, depending on the exact disease. Gaucher disease is characterized by a wide array of symptoms, and the severity of the disease ranges from undetectable to lethal.

Three forms of the disease are recognized: Types 1, 2, and 3. Type 1 is by far the most common and shows the mildest symptoms. It is non-neuronopathic, meaning that the central nervous system (brain and spinal cord) is not affected. The onset of Type I can occur at any age in childhood or adult life, with the average age of onset at about age 21. Some affected individuals have no symptoms throughout adult life.

Type 2, known as acute neuronopathic Gaucher disease, is present at birth or in early infancy. It accounts for fewer than 1% of patients with Gaucher disease. Type 2 attacks the nervous system, causing serious and progressive brain damage, and is often fatal within the first three months of life.

Type 3, known as chronic neuronopathic Gaucher disease, generally becomes apparent during childhood. It has some of the features of both the adult and infantile forms. This affects fewer than 5% of individuals with Gaucher disease.

Gaucher disease is caused by the absence or near absence of activity of an enzyme called glucocerebrosidase (GC). The normal action of GC is to break down a common molecule called glucocerebroside. If not broken down, glucocerebroside accumulates in certain cells to levels that can cause damage. Especially affected are the spleen, liver, and bone. The cellular structures in which glucocerebroside accumulates are called lysosomes. The common link among these organs is that they house a large number of cells called macrophages. A macrophage is part of the immune system. It is a large cell that surrounds and consumes a foreign substance (such as bacteria) in the body.

Genetic profile

Gaucher disease is caused by mutations in the *GBA* gene on the long arm of chromosome 1, which provides the coding necessary to produce a protein called beta-glucocerebrosidase. This protein is responsible for creating an enzyme that breaks down a fatty substance called glucocerebroside into a useable glucose (sugar) and a simple fat molecule called ceramide. Mutations in the *GBA* gene prevent the breakdown of glucocerebroside and cause it to build up inside cells. Once the glucocerebroside reaches toxic levels, tissues and organs are damaged, leading to the symptoms of Gaucher disease.

Gaucher disease is inherited in an autosomal recessive pattern, which means that each parent of an individual with the disease must have one copy of the mutated gene and pass this copy on to their child. The parents typically do not show signs or symptoms of the disease. Persons with only one gene mutation are carriers for the disorder. A person who is a carrier for Gaucher disease does not have any symptoms and does not know he or she is a carrier unless he or she has had specific testing. When both parents are carriers for Gaucher disease, there is a one in four chance (25%) in each pregnancy for a child to have Gaucher disease. There is a 50% chance that a healthy child of two parents who are carriers will be a carrier of the disease.

Genetic counseling is advised for individuals with Gaucher disease, and for their relatives, to accurately assess risk and discuss testing options. For couples who have previously had a child with Gaucher disease, or in situations where both parents are carriers for known Gaucher mutations, prenatal genetic testing is available to determine whether a fetus is affected. Families in which a person has been diagnosed with Gaucher disease can have DNA testing, which enables other

KEY TERMS

Cerebrosides—Fatty carbohydrates that occur in the brain and nervous system.

relatives to determine their carrier status. Prospective parents can then use that information to conduct family planning or to prepare for a child who may have special needs.

Demographics

The three forms of Gaucher disease differ in their population genetics. Type I is most common in persons of Eastern European (Ashkenazi) Jewish descent. Among that population, the disease occurs at about a rate of about one in 450 live births, and about one in 10 to 15 persons is a carrier, making it the most common genetic disease affecting Jewish people. There are about 6,000 people with Gaucher disease in the United States. The other two types occur equally in all ethnic groups. Type 2 occurs at a rate of one in 100,000 live births, while type 3 is estimated to occur in one in 50,000 live births.

Signs and symptoms

The results of Gaucher disease are widespread in the body and include excessive growth of the liver and spleen (hepatosplenomegaly), weakening of bones, and, in acute cases, severe nervous system damage. Many patients experience bone crises, which are episodes of extreme pain in their bones because of reduced blood flow.

A wide array of other problems occur with Gaucher disease, such as anemia (lower than normal amounts of red blood cells). Just how these other symptoms are caused is not known, nor is it known why some patients have very mild disease, and others have much more significant problems. Even identical twins with the disease can have differing symptoms.

Diagnosis

Diagnosis of Gaucher disease can be confirmed by microscopic, enzymatic, and molecular tests. Biopsy

QUESTIONS TO ASK YOUR DOCTOR

- How do the three types of Gaucher disease differ from each other?
- How does the fact that the disorder is especially common among some groups affect genetic testing and genetic counseling for members of those groups?
- What is the prognosis for a child diagnosed with each of the three types of Gaucher disease?
- Are there groups or organizations from which I can obtain additional information about Gaucher disease?

(surgical removal of tissue from a problem area) of tissue is helpful for microscopic diagnosis. When biopsy tissue is examined under the microscope, cells of an individual with Gaucher disease appear swollen and show characteristic features of the cytoplasm and nucleus. Enzyme tests show deficiency (30% of normal levels) of the enzyme GC. A molecular analysis of DNA samples looking at four of the more common mutations shows defects in the gene for GC in 95% of Ashkenazi Jewish individuals and in 75% of non-Jewish people.

As of 2021, an algorithm was being tested to predict type 1 Gaucher disease in individuals in the high-risk population who show signs of enlarged spleen (splenomegaly) and/or a low blood platelet count (thrombocytopenia). The algorithm uses three measurements from a blood sample: platelet count, ferritin, and transferrin saturation. Platelets are elements of the blood involved in blood clotting. Ferritin is a blood protein that stores iron, and transferrin saturation is a measure of the amount of iron in the blood. Diagnosis can also be performed prenatally (before birth) if the parents' mutations are known by using amniocentesis or chorionic villus sampling. Diagnosis as to which of the three types of Gaucher disease an individual has is based primarily on the symptoms.

Treatment and management

Until the 1990s, only supportive therapy could be offered. Analgesics are used to control pain. Orthopedic treatment is used for bone fractures. Several treatments for anemia have been used, including vitamin and iron supplements, blood transfusions, and bone marrow transplants.

Current medical treatment for Gaucher disease includes the following:

- **Enzyme replacement therapy (ERT):** ERT has been shown to be effective for patients with type 1 Gaucher disease. Imiglucerase (Cerezyme), velaglucerase alfa (VPRIV), and taliglucerase alfa (Elelyso) are all medications approved by the Food and Drug Administration (FDA) for ERT. One of these may be injected once a week, once every three weeks, or once every other week, depending on the symptoms and option chosen. This treatment has proven especially effective in reversing the impact on organ systems; however, the associated bone disease may be slow to respond. ERT has not been shown to improve the neurologic symptoms of Gaucher disease type 2 and type 3.
- **Glucosylceramide synthase inhibitors:** The glucosylceramide synthase inhibitors miglustat (Zavesca) and eliglustat (Cerdelga) have been shown effective in treating patients with type 1 Gaucher disease who do not respond to ERT. Some individuals who have had this treatment have seen improvement in symptoms involving the spleen and liver. They have also shown improvement in platelet and hemoglobin levels.
- **Surgery:** In the past, partial or total removal of the spleen was a treatment option, but with the success of ERT, this treatment is rarely used today. However, surgery may be necessary to treat the skeletal symptoms of Gaucher disease.

Researchers continue to look for drugs to improve the treatment of Gaucher disease. Clinical trials are underway. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>.

Prognosis

A patient's expected lifespan varies greatly with the type of Gaucher disease. Infants with type 2 disease have a lifespan of a few months to as much as four years. Patients with types 1 and 3 of the disease have highly variable outcomes, with some patients dying in childhood and others living full lives. Little is known about the reasons for this variability.

Gene

Definition

A gene is the fundamental physical and functional unit of heredity. It is an individual element of an organism’s genome and determines a trait or characteristic by regulating biochemical structure or metabolic process.

Description

Genes are segments of nucleic acid consisting of a specific sequence and number of the chemical units of nucleic acids, nucleotides. In most organisms, the nucleic acid is deoxyribonucleic acid (DNA), although in retroviruses, the genetic material is composed of ribonucleic acid (RNA). Some genes in a cell are active more or less all the time, which means that they are continuously transcribed and provide a constant supply of their protein product. These are the “housekeeping” genes that are always needed for basic cellular reactions. Others may be rendered active or inactive depending on the needs and functions of the organism under particular conditions. The signal that masks or unmasks a gene can come from outside the cell—for example, from a steroid hormone or a nutrient—or it can come from within the cell itself as a result of the activity of other genes. In both

cases, regulatory substances can bind to the specific DNA sequences of the target genes to control the synthesis of transcripts.

In a paper published in 1865, Gregor Mendel (1823–1884) advanced a theory of inheritance dependent on material elements that segregate independently from each other in sex cells. Before Mendel’s findings, inherited traits were thought to be passed on through a blending of the mother and father’s characteristics, much like a blending of two liquids. The term “gene” was coined later by the Danish botanist Wilhelm Johannsen (1857–1927) to replace the variety of terms used up until then to describe hereditary factors. His definition of the gene led him to distinguish between genotype (an organism’s genetic makeup) and phenotype (an organism’s appearance). Before the chemical and physical nature of genes were discovered, they were defined on the basis of phenotypic expression, and algebraic symbols were used to record their distribution and segregation. Because sexually reproducing eukaryotic organisms possess two copies of an inherited factor (or gene), one acquired from each parent, the genotype of an individual for a particular trait is expressed by a pair of letters or symbols. Each of the alternative forms of a gene are also known as alleles. Dominant and recessive alleles are denoted by the use of higher and lower case letters. It can be predicted mathematically, for example, that a single allele pair will always segregate to give a genotype ratio 1AA:2Aa:1aa, and the phenotype ratio 2A:1aa (where A represents both AA and Aa since these cannot be distinguished phenotypically if dominance is complete).

The molecular structure and activity of genes can be modified by mutations, and the smallest mutational unit is now known to be a single pair of nucleotides, also known as a muton. To indicate that a gene is functionally normal, it is assigned a plus (+) sign, whereas a damaged or mutated gene is indicated by a minus (–) sign. A wild type *Escherichia coli* bacterium able to synthesize its own arginine would thus be symbolized as *arg*+, and strains that have lost this ability by mutation of one of the genes for arginine utilization would be *arg*–. Such strains, known as arginine auxotrophs, would not be able to grow without a supplement of arginine. At this level of definition, the plus or minus actually refers to an operon rather than a single gene, and finer genetic analysis can be used to reveal the exact location of the mutated gene.

The use of mutations in studying genes is well illustrated in a traditional genetic test called the cis-trans test, which also gave the gene the alternative name “cistron.” This is a complementation test that can be used to determine whether two different mutations (m1 and m2) occur in the same functional unit, i.e., within the same gene or cistron. It demonstrates how genes can be defined

phenomenologically and has been performed successfully in microorganisms such as yeasts.

It works on the principle that pairs of homologous chromosomes containing similar genes can complement their action. Two types of heterozygotes of the test organism are prepared. Heterozygotes are organisms with different alleles in the two homologous chromosomes, each of which was inherited from one parent. One heterozygote contains the mutations under investigation within the same chromosome, that is in the *cis*-configuration, which is symbolically designated ++/m1m2 (m1 and m2 are the two mutations under investigation, and the symbol “+” indicates the same position on the homologous chromosome in the unmutated, wild type state). The second mutant is constructed to contain the mutations in such a way that one appears on each of the homologous chromosomes. This is called the *trans*-configuration and is designated, for example, by m2+/+m1.

If two recessive mutations are present in the same *cis*-tron, the heterozygous *trans*-configuration displays the mutant phenotype, whereas the *cis*-configuration displays the normal, wild type phenotype. This is because in the *cis*-configuration, there is one completely functional unmutated *cistron* (++) within the system, which masks the two mutations on the other chromosome and allows for the expression of the wild type phenotype. If one or both mutations are dominant, and the *cis*- and *trans*-heterozygotes are phenotypically different, then both mutations must be present in the same *cistron*. Conversely, if the *cis*- and *trans*-heterozygotes are phenotypically identical, this is taken as evidence that the mutations are present in different *cistrons*.

In 1910, the American geneticist Thomas Hunt Morgan (1866–1945) began to uncover the relationship between genes and chromosomes. He discovered that genes were located on chromosomes and that they were arranged linearly and associated in linkage groups, with all the genes on one chromosome being linked. For example, the genes on the X and Y chromosomes are said to be sex-linked because the X and Y chromosomes determine the sex of the organisms (in humans X determines femaleness and Y determines maleness). Nonhomologous chromosomes possess different linkage groups whereas homologous chromosomes have identical linkage groups in identical sequences. The distance between two genes of the same linkage group is the sum of the distances between all the intervening genes. A schematic representation of the linear arrangement of linked genes, with their relative distances of separation, is known as a genetic map. In the construction of such maps, the frequency of recombination during crossing over is used as an index of the distance between two linked genes.

Advances in molecular genetics have allowed analysis of the structure and biochemistry of genes in greater

detail. They are no longer the nebulous units described by Mendel purely in terms of their visible expression (phenotypic expression). It is now possible to understand their molecular structure and function in considerable detail.

The biological role of genes is to carry, encode, or control information on the composition of proteins. The proteins, together with their timing of expression and amount of production, are possibly the most important determinants of the structure and physiology of organisms. Each structural gene is responsible for one specific protein or part of a protein, and codes for a single polypeptide chain via messenger RNA (mRNA). Some genes code specifically for transfer RNA (tRNA) or ribosomal RNA (rRNA) and some are merely sequences that are recognized by regulatory proteins. The latter are termed regulator genes. In higher organisms, or eukaryotes, genes are organized in such a way that at one end there is a region to which various regulatory proteins can bind, for example, RNA polymerase during transcription, and at the opposite end there are sequences encoding the termination of transcription. In between lies the protein encoding sequence. In the genes of many eukaryotes this sequence may be interrupted by intervening non-coding sequence segments called introns, which can range in number from one to many. Transcription of eukaryotic DNA produces pre-mRNA containing complementary sequences of both introns and the information carrying sections of the gene called exons. The pre-mRNA then undergoes post-transcriptional modification or processing in which the introns are excised and exons are spliced together, leaving the complete coding transcript of connected exons ready to code directly for the protein.

When the central dogma of genetics was first established, a “one gene—one enzyme” hypothesis was proposed, but today it is more accurate to restate this as a one-to-one correspondence between a gene and the polypeptide for which it codes. This is because a number of proteins are now known to be constituted of multiple polypeptide subunits coded by different genes.

Gene editing

Gene editing (also called genome editing) refers to technologies that scientists can use to change an organism's DNA. Through a group of techniques, scientists can add, remove, or modify genetic material at specific locations in the genome. It is one aspect of gene therapy, which is replacement of faulty genes or an addition of genes to help cure or manage a disease.

Description

Gene-editing work began by editing genomes of organisms such as yeast and bacteria, and animals such as mice and zebrafish. Several approaches to gene editing have been attempted, many of which have proved lengthy and expensive to complete. With gene editing, there is the possibility of making changes to an individual's DNA, and therefore possibly to the DNA of future generations. Most of the technologies work like scissors to cut the DNA at a predetermined specific spot. Scientists then can remove, add, or replace genetic material where the cut was made.

Rapid advancements

The first gene editing technologies appeared in the late 1900s. Early strategies were based on nuclease systems to eliminate disease-causing genes or to repair damaged or mutated ones. Others have targeted DNA-binding proteins or meganucleases (nucleases with long DNA-bind recognition sites). Homologous recombination, an early genome-editing method that exchanged genetic information between two homologous DNA strands, was inefficient in most cell types, with a low probability that the technique would edit successfully. Zinc-finger nuclease editing improved specificity somewhat but was a difficult method to design and construct. Transcription-activator-like effector nucleases are a class of proteins used in genome editing that have offered similar effectiveness to zinc-finger nuclease editing but with a simpler design and construct.

CRISPR-Cas9

One approach to gene editing that has generated much interest since its 2009 development is called clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated protein 9 (Cas9). Based on RNA targeting, the technology is a simpler, faster, and less expensive way to edit genes, while also being more accurate than past methods. Scientists adapted CRISPR-Cas9 technology from a genome-editing system that occurs naturally in bacteria. When bacteriophages (viruses that attack bacteria) invade, bacteria capture tiny pieces of DNA from them and create DNA segments, which help the bacteria remember the virus. These bacteria are then able to respond to future attacks by recognizing the segments and releasing the DNA-cutting protein Cas9, which snips the genetic code of the invader.

Genome-editing methods

CRISPR technology has improved on past genome-editing methods. Within months of the new method's release, six independent reports discussed use of the system for programmable gene editing in vivo. Ex vivo gene editing removes cells from a patient, corrects them, and

then places the corrected cells back into the patient via autologous transplantation. With in vivo editing, the patient receives injected vectors containing therapeutic elements.

Applications

Scientists have begun to develop gene therapies involving gene editing. Most research as of 2021 has focused on understanding diseases by using cells and animal models.

Laboratory

In laboratories, researchers can use genome editing to study diseases affecting humans. They edit the genes of animals such as mice, because many of the genes are similar across species (mice and humans share about 85 percent of their genes). By editing a single gene or several, researchers can observe the effects of the changes on the mouse's health to apply findings to understanding the pathology of human disease and to develop effective treatments.

Treating disease

Targeting of cells to treat diseases such as cancer has been an improvement in therapy. However, past gene therapy delivery has relied on viruses to introduce a functional transgene, since viruses have a natural ability to enter cells. Their capacity is limited, however. With nuclease-based genome editing, scientists can make targeted disruption (inactivation) of a coding sequence, substitute nucleotides successfully, target insertion of a transgene, or target alterations to non-protein coding genetic elements. In addition, the methods lead to creation of large deletions at chosen locations in the genome.

Germline gene editing

Many diseases, such as diabetes and cystic fibrosis, have a strong genetic basis. Germline gene editing involves reproductive cells. Editing of gametes or early embryos would propagate the resultant changes through

future cells of the organism. They then might be inherited by future generations, which could address hereditary diseases passed on from one generation to the next. Use of CRISPR-Cas9 can generate nuclease-induced double-stranded breaks in DNA (DSBs). These then can be repaired through homology-directed repair (HDR) or nonhomologous end-joining (NHEJ). Using CRISPR-Cas9 through NHEJ or high-fidelity HDR pathways can target genomic modifications, allowing introduction of small insertions and deletions.

Somatic gene editing

Gene editing of somatic cells (all cells other than reproductive ones) also can treat some hereditary diseases but only affect the genes of the treated individual, not passing of the disease to future generations. Applications of somatic gene editing have been at various stages of clinical development and include:

- HDR editing ex vivo to edit a non-disease-causing variant of sickle cell disease.
- In vivo HDR to express clotting factor from a strong promoter of hemophilia B.
- NHEJ editing of T-cells ex vivo to engineer resistance to HIV.
- Cancer immunotherapy in T-cells ex vivo with HDR or NHEJ to engineer more potent cancer-specific T-cells for genome editing.
- NHEJ editing in vivo to delete disease-causing expanded triplet repeat involved in Huntington's disease.

In May 2021, an example of gene-editing experiments was announced that could help restore vision to people who have a rare condition known as Leber congenital amaurosis. It was a first for editing genes in vivo, using CRISPR instruction methods delivered via viruses.

Ultimately, scientists hope that CRISPR-Cas9 methods can help remove malignant mutations from cancer patients and replace them with normal DNA sequences. As of 2020, initial success had been observed in working with leukemia and colon cancer models to promote cancer therapies. Gene editing could address infectious diseases as well. Studies also have revealed potential for treatment or prevention of some cardiovascular, metabolic, and neurodegenerative diseases through gene editing.

Ethics and acceptance

Although still in its infancy, gene editing shows breakthrough promise in disease prevention and treatment. Still, technical and ethical challenges remain. For example, as precise as CRISPR is, sometimes genome-editing tools target the wrong spot, and the errors could have consequences in patients. Therefore, assessing

safety and improving techniques are essential parts of future applications. Much of the laboratory work involving animals shows promise and advancement, but scientists also must determine whether the findings apply safely and effectively to treating disease in humans.

The ethics of gene editing are complex, affecting decisions made at laboratory and treatment points. Patient safety is foremost, as is informed consent. As a relatively new approach to medicine, gene-editing standards and regulation are still in development.

Germline gene editing in particular raises a number of ethical issues. On the one hand, safe and effective editing of germline genes could offer hope for families with inherited mutations leading to serious diseases and conditions by eliminating these mutations from their gene pool. In addition, enhancing traits such as resistance to infectious diseases could improve public health. Much debate about risks versus benefits is likely to continue, and the scientific community is approaching the technology with caution. Although editing these genes could address many inherited diseases, use of the technology to enhance human traits is unethical, and general agreement weighs against editing the genomes of germline cells as of 2021. Use of germline gene editing is largely considered premature until studied further, and its use is illegal in many countries.

Researchers continue to harness the rapid and effective results from CRISPR-Cas9 methods to learn how to modify, insert, or delete genetic material at precise locations. Eventually, the choices that scientists confront and the ethical decisions that scientists and policymakers must make will become more apparent.

Gene fusion

Definition

Gene fusion is an alteration of genetic material from one or more events that exchange genetic information. These events typically occur in a developing embryo when genetic information is being replicated. A fusion of a gene may cause a wide variety of changes depending on the type and amount of genetic material lost or altered.

Description

Gene fusion is an abnormal event that occurs between genes on one or more chromosomes where genetic data are altered. This may occur due to a translocation event between chromosomes, an inversion event on one chromosome, or an interstitial deletion on one chromosome. Gene fusion can carry many implications depending on the alteration of the chromosomes and the rearrangement of the genetic data. Genetic data may be completely lost, partially lost, or—in most cases of cancer due to gene fusions—the expression of genetic data may be abnormally regulated, resulting in overexpression or underexpression of genes.

Recent research has determined that fusion of genes is associated with many forms of cancer. An understanding of the fusion has led to a more efficient and more effective treatment approach for these cancers.

Genetic profile

The first observance of gene fusion occurred in 1960 with the discovery of the Philadelphia chromosome associated with chronic myelogenous leukemia. Researchers found an alteration in chromosomes 9 and 22 due to a translocation event. This event transferred genetic material from chromosome 22 to chromosome 9, causing a shortening of 22 and an elongation of 9. The genetic data were fused on each chromosome, resulting in a *BCR-ABL* fusion gene. Since this first discovery, more research has been done on gene fusion events and the implications they have on the human body, specifically in regard to cancer. There are three mechanisms by which gene fusion may occur: translocation, interstitial deletion, or chromosomal inversion.

Translocation of genes may occur between chromosomes and have no negative implications. This will occur if the event is balanced and no genetic material is lost. The event is considered unbalanced if genetic material is lost and leads to an alteration in the expression of genes and proteins. An unbalanced translocation event on or between autosomal chromosomes is associated with disorders such as Down syndrome, leukemia, and other

KEY TERMS

Interstitial deletion—The deletion of a piece of one chromosome.

Inversion—A type of chromosomal defect in which a broken segment of a chromosome attaches to the same chromosome but in reverse position.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosome material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

forms of cancer. An unbalanced translocation event on or between sex chromosomes is associated with XX male syndrome due to the translocation of the *SRY* gene from the Y chromosome to the X chromosome, resulting in the expression of the *SRY* gene on the X chromosome.

Interstitial deletion of genetic information occurs when a portion of a chromosome is abnormally spliced, and the material on each side of the spliced site is fused together. This results in an abnormally shortened chromosome with missing genes. The phenotype of this event will be observed depending on the genetic material that is missing and any new or altered expression that may or may not occur.

Chromosomal inversion occurs within a single chromosome. Genetic material is spliced, the material is inverted (flipped), and then the material is reconnected to the same chromosome. If this inversion involves the centromere, it is referred to as pericentric inversion. If it does not involve the centromere, it is referred to as paracentric inversion. Much like the other two fusion events, the result of any chromosomal inversion will be determined by the genetic material altered.

Demographics

The presence of a gene fusion in different types of cancer varies. Research has shown that about 50% of prostate cancers are due to a gene fusion of *TMPRSS2-ERG*; and roughly 95% of all acute promyelocytic leukemia cases are due to a gene fusion event of *PML-RAR*.

Signs and symptoms

Gene fusion events may lead to a variety of disorders or none at all. An event that removes critical genetic

- What are the chances my children or siblings will have a gene fusion event?

material from a developing fetus may cause termination of the fetus. An event that causes a balanced fusion may have no implications and therefore no signs, symptoms, and/or pathology. Recent research has shown that multiple types of cancers are due to gene fusions on autosomal chromosomes. These cancers include breast cancer (such as *BCAS3-BCAS4* gene fusion), lung cancer, colon cancer, prostate cancer (such as *TMPRSS2-ERG* gene fusion), ovarian cancer, and multiple types of leukemia (*BCR-ABL* fusion gene in chronic myelogenous leukemia [CML]). Some of these cancers result from an upregulation of tyrosine kinase as coded by the fusion gene. Tyrosine kinase functions as an “on/off” switch for many cellular functions. When the tyrosine kinase is overactive on the “on” position, an overgrowth of cells occurs, leading to tumors and therefore cancer.

Diagnosis

Genetic testing can be performed to determine whether a gene fusion has occurred. This may include Sanger sequencing, PCR testing, fluorescence in situ hybridization (FISH), and/or whole-transcriptome sequencing (WTS). These testing methods have been successful in children with acute myeloid leukemia (AML) and in adults with prostate cancer. The hybrid sequencing approach has been useful in detecting gene fusion and the location of that fusion in patients with breast cancer. Gene fusions are very important biomarkers for cancer because they are always abnormal when present.

Treatment and management

Treatment and management of a gene fusion is based upon the genes involved and the clinical manifestations of the resulting fusion. CML, breast cancer, and prostate cancer due to a gene fusion event have recently been treated with tyrosine kinase inhibitors imatinib, dasatinib, and nilotinib, all of which have had some success. Tyrosine kinase inhibitors work to decrease the activity of tyrosine kinase by competing with the activation site on

the enzyme. If the inhibitor binds to the activation site on the enzyme, the enzyme will not perform its coded function. Other tyrosine kinase inhibitors include sunitinib, gefitinib, and erlotinib for lung and pancreatic cancers.

Prognosis

The prognosis of a gene fusion event is fully dependent on the amount and type of genetic material lost or altered. The presence of the fusion gene *TMPRSS2-ERG* in prostate cancer, for example, has a poor prognosis due to the clinical manifestations and the lack of treatment options. Drug resistance to tyrosine kinase inhibitors may also be a factor in the prognosis of cancers and other pathologies related to gene fusion events.

Gene mutations

Definition

In a strict sense, mutations are changes in genes not caused by genetic recombination. A change in the base sequence of DNA, for example, represents a mutational change. Spontaneous mutations are mutations that occur at a given frequency without the need for an inducing agent of change (mutagenic agent). The term “mutation”

An x-ray of feet with six toes each, a condition known as polydactyly. It results from a genetic mutation. (Chris Bjornberg/Science Source)

is also used in a less technical sense to describe changes in the human genome (that is, evolution) that result from a broad spectrum of processes that act to increase or decrease genetic variation within a population.

Description

By definition, a gene is a hereditary unit that carries information used to construct proteins via the processes of transcription and translation. The human gene pool is the set of all genes carried within the human population. Genetic changes, including mutations, can be beneficial, neutral, or deleterious. In general, mutations, along with recombination and gene flow, act to increase genetic variation (i.e., the number of types of genes or alleles) within the human species.

The term “mutation” was originally used by the Dutch botanist Hugo De Vries (1848–1935) to describe rapid changes in phenotype from one generation to the next. Subsequently, scientists used the term “mutation” to describe long-term, multi-generational, and heritable physical changes to genes.

Mutations generally occur via chromosomal mutations, point mutations, frame shifts, and breakdowns in DNA repair mechanisms. Chromosomal mutations include translocations, inversions, deletions, and chromosome non-disjunction. Essentially there are five types of genetic rearrangements: deletions, duplications, inversions, translocations, and transposition.

Mutational deletions physically remove portions of genes (e.g., a portion of the DNA comprising the gene). Deletional mutations range from the single base point mutations to mutations that can span many functional genes. Chemical and radioactive agents account for the majority of induced point mutations. Scientists currently maintain that most cancers and other degenerative

diseases result from acquired genetic mutations due to environmental exposure, and not as an outcome of inherited traits. Chemicals capable of inducing genetic mutation (i.e., chemical mutagenesis or genotoxic compounds) include a wide variety of natural and man-made products.

Point mutations may be nonsense mutations leading to the early termination of protein synthesis; missense mutations (a mutation that results in a substitution of one amino acid for another in a protein); or silent mutations that cause no detectable change. Accordingly, the effects of point mutational changes range from 100% lethality (all individuals die, usually early in fetal development) to no observable (phenotypic) change.

Duplications result in multiple copies of genes, and can occur as a result of unequal crossover or chromosome breaks. In addition, because some alteration of DNA is inevitable in the replication process, any mutation that hinders the DNA repair mechanism increases the chance that a mutation will go uncorrected. Duplications also manifest a range of deleterious effects.

Inversions (changes in the orientation of gene bearing chromosomal regions) may cause deleterious effects if the inversion breaks through a gene critical to a particular protein or enzyme.

Translocations occur when a portion of one chromosome becomes linked to a non-homologous chromosome (a chromosome outside its normal pairing), or when portions of non-homologous chromosomes make a reciprocal exchange. Once again, the effect of such genetic change is a result of whether such translocations physically or functionally alter vital genes.

Recombination involves the reassortment of genes through new chromosome combinations. Recombination occurs via an exchange of DNA between homologous chromosomes (crossing over) during meiosis. Recombination also includes linkage disequilibrium. With linkage disequilibrium, variations of the same gene (alleles) occur in different combinations in the gametes (sexual reproductive cells) than should occur according to the rules of probability.

Gene flow occurs when individuals change their local genetic group by moving from one place to another. These migrations allow the introduction of new variations of the same gene (alleles) when they mate and produce offspring with members of their new group. In effect, gene flow acts to increase the gene pool in the new group. Because genes are usually carried by many members of a large population that has undergone random mating for several generations, random migrations of individuals away from the population or group usually do not significantly decrease the gene pool of the group left behind.

In contrast to mechanisms that operate to increase genetic variation, there are fewer mechanisms that operate to decrease genetic variation. Mechanisms that decrease genetic variation include genetic drift and natural selection.

Genetic drift results from the changes in the numbers of different forms of a gene (allelic frequency) that result from sexual reproduction. Genetic drift can occur as a result of random mating (random genetic drift) or be profoundly affected by geographical barriers, catastrophic events (e.g., natural disasters or wars that significantly affect the reproductive availability of selected members of a population), and other sociopolitical factors.

Natural selection is based upon the differences in the viability and reproductive success of different genotypes with a population (differential reproductive success). Natural selection can only act on those differences in genotype that appear as visible (phenotypic) differences that affect the ability to attract a mate and produce viable offspring that are in turn able to live, mate, and continue the species. The term “evolutionary fitness” describes the success of an entity in reproducing (i.e., contributing alleles to the next generation).

There are three basic types of natural selection. With directional selection, an extreme phenotype is favored (high or low body fat). Stabilizing selection occurs when an intermediate phenotype is fittest (for example, body fat content is neither too high nor too low), and for this reason, it is often referred to a normalizing selection. Disruptive selection occurs when two extreme phenotypes are more fit than an intermediate phenotype. In studying changes in the human genome, the operation of natural evolutionary mechanisms is complicated by geographic, ethnic, religious, and social groups and customs. Accordingly, the effects of various evolution mechanisms on human populations are not as easy to predict. Increasingly sophisticated statistical studies are carried out by population geneticists to characterize changes in the human genome.

Gene panel testing

Definition

Gene panel testing is a laboratory technique for detecting mutations or variations in the DNA sequences of specific genes. Gene panels usually test simultaneously for different variations in multiple genes.

Purpose

There are many different gene panels used for a variety of purposes. Gene panel testing offers numerous advantages over conventional DNA sequencing of individual genes:

- Many different genes can be tested simultaneously.
- Many different mutations or variations (heterogeneity) in a single gene can be tested for simultaneously.
- Larger genes can be readily analyzed.

Diagnostic gene panel testing can definitively diagnose a genetic disorder and identify the specific gene mutation responsible for the disorder. It can also rule out a genetic disorder as the cause of symptoms. This knowledge can inform decisions about treatment and management. For example, gene panel testing can clarify a diagnosis of inherited heart disease, identify the cause of familial heart disease, and predict which family members are at risk for developing the disease. At-risk family members can then have periodic screenings and make lifestyle changes that may reduce their risk of heart disease.

Newborn screening for genetic disorders facilitates early treatment and management if a disorder is detected. For example, all newborns are tested for congenital hypothyroidism and phenylketonuria (a genetic disorder that if left untreated causes intellectual disability). In most

states, newborns are also tested for other genetic disorders.

Predictive or presymptomatic gene panel testing can detect gene mutations that increase the likelihood of developing a disease later in life. If a family member has a genetic disorder, predictive testing may indicate whether other family members will eventually develop a disorder such as hereditary hemochromatosis (iron overload in the body). For example, perhaps 5%–10% of the population is at higher risk for developing cancer because of specific inherited mutations. Such people tend to develop multiple cancers at an unusually young age. As of 2021, more than 50 hereditary cancer syndromes had been identified, including hereditary colorectal, breast, and uterine cancers; diffuse gastric cancer; Li-Fraumeni syndrome; and childhood Fanconi anemia. Multigene panel testing can detect inherited mutations in various genes that are associated with these cancers. Gene panel testing can also identify genetic variations that may increase susceptibility to a variety of disorders, including Alzheimer's disease. These types of gene panel testing may help people make decisions about their future medical care.

Reproductive gene panel testing can determine whether an embryo or fetus has a genetic disorder. Preimplantation gene panel testing is performed in conjunction with assisted reproductive technologies such as in vitro fertilization. A few cells are removed from the embryo and tested prior to implantation in the mother's uterus, thereby reducing the risk of a child with a genetic disorder. Prenatal gene panel testing may be offered to parents who are at increased risk of having a child with a genetic disorder. Negative results can reduce parental anxiety. Positive results provide parents with options, such as terminating the pregnancy or preparing for delivering and caring for a child with a disorder. For example, early detection of cystic fibrosis (CF) enables parents to plan for early monitoring and specialized care and treatment that can minimize complications and improve the child's prognosis and quality of life.

Cancers are caused by various multiple gene mutations in one or a few cells that enable them to grow uncontrollably. Specific cancer-causing mutations may respond to targeted cancer drug treatments. Gene panel testing of a tumor biopsy specimen can help identify the cancer type or subtype and select the most effective treatment. Cancer gene panel testing is also used to monitor responses to treatment and predict prognoses.

Description

Many different gene panels are used in clinical and research laboratories, and some are marketed directly to

consumers. Different panels test for mutations or variants in a single gene, a few different genes, or a large number of genes simultaneously. In addition to testing for genetic disorders, predisposition to diseases, and cancer-causing mutations, some gene panels are designed to determine familial relationships and ancestry. As new genes and mutations that cause or contribute to various diseases are discovered, they are added to existing gene panels.

Gene panel testing is performed on DNA (or sometimes RNA) that has been extracted from a variety of specimen types:

- blood
- urine
- saliva
- cells scraped from the inner cheek (a buccal swab)
- bone or other body tissues
- hair
- fetal cells obtained by chorionic villus sampling (CVS) or amniocentesis
- fetal cell-free DNA in maternal blood
- cancerous tumor cells from a biopsy

In the laboratory, the cells are isolated and broken, and the DNA is extracted. DNA sequences of suspected disease-causing or disease-susceptibility genes are compared with the DNA sequences of standard "normal" genes. The DNA is prepared for testing in different ways, depending on the gene panel technology. Enzymes can cut DNA into small pieces containing the gene(s) of interest. DNA of interest may be amplified to produce many copies and sequenced to determine the order of nucleotides (building blocks of DNA). Some gene panels are chips with DNA "probes" that "hybridize" to specific genetic variations in the samples. Others are chromosome microarrays for detecting chromosomal abnormalities. High-throughput next-generation ("next-gen") DNA sequencing has facilitated parallel sequencing of multiple genes simultaneously. Multigene panel ("multiplex") testing was introduced in the United States in 2013. It analyzes dozens of genes simultaneously at a cost that is comparable to analyzing a single gene. It accomplishes this by sequencing millions of short pieces of DNA, which are then compiled into genes using bioinformatic techniques. Prior to the advent of next-gen sequencing, gene panel testing for disease-causing mutations usually analyzed only genes that were known to be most commonly involved in a disorder. As of 2021, next-gen sequencing panels were available for cardiovascular and neurologic diseases, mitochondrial disorders, reproductive testing, and cancer genes.

Diagnostic panels

Panels for genetic or hereditary conditions generally test for specific mutations in one or a few genes that are inherited in standard Mendelian fashion. They are used for diagnosis, for defining the underlying mutation causing the disorder, or for risk assessment in individuals without symptoms. Panels usually include the most common mutations known to cause a specific disorder. For example, a panel for pathologic mutations causing hypertrophic cardiomyopathy will not include mutations associated with other cardiovascular disorders. Some panels contain mutations associated with multiple related conditions; for example, a pan-cardiomyopathy panel may include pathologic mutations for both hypertrophic cardiomyopathy and other types of cardiomyopathy. Some panels test for mutations associated with multiple diseases that result in similar clinical syndromes. Such panels can provide a specific diagnosis among several potential underlying diseases with similar symptoms, such as intellectual disability.

The newest gene panels may far exceed these descriptions. For example, the Targeted Gene Sequencing and Custom Analysis (TaGSCAN) test can identify about 95% of known gene mutations that trigger more than 750 diseases in children. The screening panel covers 514 genes associated with severe hereditary disorders, many of which are difficult-to-diagnose neurodevelopmental, immune system, and metabolic disorders and intellectual disabilities. A computer program selects the genes to be analyzed based on symptoms and family history.

Reproductive panels

Reproductive panels test for gene mutations associated with inherited genetic disorders. Preconception testing is most often performed for autosomal recessive mutations in potential parents who are at risk because of a family history. Preconception screening is sometimes performed for potential parents with no known risk factors. Prenatal testing via CVS or amniocentesis for mutations associated with a single disorder is generally used when there is a family history of a disorder. When there is no family history of an inherited disorder, prenatal screening or microarray panels usually include common mutations associated with multiple disorders. Fetal DNA obtained from maternal blood is used to screen for chromosomal aneuploidies (too many or too few chromosomes).

One of the most commonly used gene panels tests for mutations in the *CFTR* gene that cause CF. CF is an autosomal recessive disorder, so children with CF have inherited two mutated *CFTR* genes—one from each parent. The parents are carriers, each with one copy of a mutated *CFTR* gene but no symptoms of disease; however, each

of their children has a 25% risk of inheriting both mutated genes and having CF. As of 2021, more than 1,500 mutations had been identified in the *CFTR* gene, but only a few of these are common. The standard CF gene panel includes 23 of the most common mutations (occurring in more than 0.1% of the general U.S. population). Expanded panels may include 100 or more mutations to detect rare CF-causing mutations that are common to specific ethnic groups. CF gene panel testing is used as a carrier screen in the general population and high-risk subsets of the population, as well as to confirm CF diagnoses. The American College of Obstetricians and Gynecologists recommends that CF carrier screening be made available to all women of reproductive age. Fathers are not tested unless the mother tests positive for a *CFTR* mutation. If both parents are known carriers with identified *CFTR* mutations, preimplantation screening or prenatal diagnosis may be performed.

Cancer panels

Since the 2013 U.S. Supreme Court decision that invalidated patents on human genes, commercially available cancer gene panels have proliferated, and there are many more options for gene panel testing of tumor mutations. Cancer gene panels employ next-generation sequencing technologies to simultaneously test for inherited (germline) and somatic (acquired) mutations in multiple genes to assess cancer risk in people without symptoms who have a family history or other clinical indications. Panels with multiple somatic (acquired) mutations that are associated with various types of cancer are used to test tissue samples from patients' tumors to help select drugs that target specific mutations. Cancer panels vary in size from just the two inherited breast cancer susceptibility genes—*BRCA1* and *BRCA2*—to more than 50 different genes. Cancer gene panels have greatly improved the efficiency and decreased the cost of cancer genetic testing.

Precautions

Gene panel testing should be approached with caution:

- It is not available for all genes and genetic conditions, and cannot identify all inherited disorders and birth defects.
- The panels are not standardized; different commercial gene panels for the same condition may test different genes.
- Positive results from gene panel testing for susceptibility genes—and even for some causative genes—do not mean that an individual will necessarily develop the disease.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Carrier testing—Testing performed to determine whether someone possesses one changed copy and one unchanged copy of a particular gene.

Chorionic villus sampling (CVS)—A procedure involving removal of a small placenta sample during pregnancy to obtain fetal chromosome results.

Cystic fibrosis (CF)—A respiratory disease characterized by chronic lung disease, pancreatic insufficiency, and an average age of survival of 20 years. Cystic fibrosis is caused by mutations in a gene on chromosome 7 that encodes a transmembrane receptor.

Germline mutation—A heritable change in the DNA of a germ cell (a cell destined to become an egg or in the sperm). When passed from one generation to the next, a germline mutation is incorporated in every cell of the body.

Microarray—A supporting material (usually glass or plastic) to which DNA fragments of known sequence are attached for the identification and sequencing of DNA samples.

Somatic mutations—*De novo* mutations that are acquired throughout life and affect only some cells in the body.

- A positive gene panel diagnostic test, such as for CF, confirms the diagnosis but does not predict how serious the disease will be, since even patients with identical gene mutations can have very different outcomes.
- The clinical significance of mutations and genetic variations detected by expanded gene panels is often unclear, and the number of detected variants increases as next-generation sequencing examines a larger portion of a person's genome.
- Gene panel tests can be marketed to consumers and clinicians without proof that detected gene variants are associated with disease risk.

- Misinterpretation of uncertain results by clinicians can lead to unnecessary and potentially harmful interventions and treatments.
- New sequencing technologies have a higher error rate than conventional direct DNA sequencing; thus they may be less accurate and increase the rate of false-positive results.
- Gene panel testing should be performed by a laboratory licensed for high-complexity testing. The accuracy of next-generation-sequencing gene panel testing should be comparable to that of conventional direct DNA sequencing.
- Although negative results can relieve anxiety, positive results can lead to a wide range of emotional responses, including anger, guilt, grief, fear, and depression.
- Gene panel testing is expensive and may not be covered by insurance.
- Many conditions for which gene panel testing is available are neither preventable nor treatable.
- Although predictive results from gene panel testing cannot be used to discriminate against people for employment or health insurance, in some circumstances, the results may be used to deny life insurance or long-term-care or disability insurance.

Gene panel testing for cancer susceptibility has only recently become clinically available, and there are no set guidelines for who should be offered testing. Furthermore, the results of cancer gene panel testing are becoming increasingly complex. The significance of gene variants is often unknown, and even clearly harmful mutations may be of uncertain clinical significance. The risk of uncertain results increases with the number of genes and mutations included in a panel. For example, most of the more than 100 genes included in some breast cancer gene panels have no known association with breast cancer—variants in only nine genes other than *BRCA1* and *BRCA2* have been linked to breast cancer. Furthermore, a 2015 study reported that up to half of cancer patients may not receive the most appropriate treatment if gene panel testing is performed only on their cancer tissue; rather, gene variants detected in tumor tissue must be compared to genes in the patient's normal tissue to confirm that they are involved in the cancer. The study reported that these false-positive results affect about 50% of cancer patients who have gene panel testing.

Preparation

The decision to undergo gene panel testing is a personal choice. Patients should consult with an experienced healthcare provider or genetic counselor who can discuss the benefits and pitfalls of testing. Patients should consider beforehand how they might react to positive and negative test results. Since gene panel testing often

QUESTIONS TO ASK YOUR DOCTOR

- Under what circumstances do you recommend gene panel testing?
- What type of gene panel testing do you recommend?
- Do you work with a specific genetic testing laboratory?
- Can you recommend a genetic counselor?
- Will my insurance pay for gene panel testing?

includes multiple family members, it can affect family relationships; for example, some family members may not want to be tested or may not want to share their genetic status.

Gene panel testing requires obtaining blood, urine, tissue, or other material from the patient. Fetal testing may require CVS or amniocentesis. Cancer panel testing may require a tumor biopsy.

Aftercare

Patients should consult a genetic counselor or specialist who can accurately interpret the results of gene panel testing and discuss future options, if necessary.

Results

Depending on the panel, results are available in a few weeks or months.

- Positive results mean that the laboratory is reasonably confident that it has identified a gene mutation that confirms a diagnosis, can guide treatment, or is associated with risk for a genetic disorder. The latter result may indicate steps that might help prevent the condition from developing. In some cases, a positive result indicates that other family members may want to be tested.
- Negative results only mean that a known disease-causing mutation was not found in the genes tested. A genetic cause or susceptibility may not have been detected because of the technology used; because the responsible gene was not analyzed; or because a rare mutation was not identified by the panel.
- Inconclusive results indicate that a mutation or variation was found, but its significance is unknown. This type of result is often referred to as a variant of unknown significance (VUS). However, it is possible that new

information concerning a VUS will become available in the future.

- If a gene panel test is negative or inconclusive, but the patient has symptoms, additional testing may be warranted.

Healthcare team roles

Laboratory professionals who perform and interpret gene panel tests are specially trained physicians and scientists. A geneticist or genetic counselor, as well as a specialist in the disease or disorder, should be involved in a patient's decision to have gene panel testing and in the interpretation of results.

Gene pool

Definition

The term "gene pool" refers to the total sum of genetic information present in a population at any given time. A gene pool can be assigned to any set group or population. This is true for plants, animals, and humans alike. Each gene pool contains all of the inherited information for all of the traits of the members of the population.

Genetic information

Genetic information in the form of deoxyribonucleic acid (DNA) is passed down from generation to generation. DNA tells a person's body how to work and how to grow. It provides instructions that assign features to each individual, such as giving one person brown hair and another person blonde hair, and one person brown eyes and another person green eyes.

DNA is much like a linear string, with individual segments along the string known as genes. Genes provide the specific directions for the body. Each gene is a segment of DNA, and sequencing of the four base molecules of DNA create the gene. Variations in the sequence account for variations in genes. A gene is a unit of hereditary information with alternate versions known as alleles; each particular gene is found on the same chromosome in each individual. The long, linear strings of DNA are arranged into smaller packages known as chromosomes. In general, there are 46 chromosomes in each cell of a person's body. The 46 chromosomes can be matched into 23 pairs. One of each pair is inherited from the mother's egg and one of each pair is inherited from the father's sperm. Most animals, including humans, contain two copies of each chromosome and likewise two copies of each gene. Each individual receives one allele from each parent because they receive one of each of the 23 chromosomes from each parent.

Although each person has 46 chromosomes, the DNA that makes up those chromosomes is slightly different from individual to individual. It is this variation within specific genes that gives the diversity observed throughout populations around the world.

Alleles

Different versions of the same gene are referred to as alleles. Blood types are examples of alleles. In humans there are several different blood types, including A, B, O, and AB. These arise by various combinations of the three blood-type alleles: the A-allele, the B-allele, and the O-allele. The specific blood type a person has depends on the exact blood type alleles they inherited from their parents. For example, a person may inherit two O-alleles, in which case they would have type O blood, or they may inherit an A- and a B-allele, in which case they would have type AB blood, and so on.

Population genetics

Population genetics is the study of genetic variation within a population. This includes the subtle changes in DNA sequences and the frequencies of these different forms. Changes within the DNA sequences may arise through several pathways. Mechanisms commonly

studied by population geneticists include mutation, natural selection, and genetic drift.

Mutations are changes within the DNA sequence that alter the original directions encoded within DNA. Mutations may result from damage to DNA, or a mistake in the replication of DNA resulting in a sequence change. The majority of mutations arise by chance, although some may be caused by environmental factors, such as toxins that penetrate the cells of the body and attack the DNA. Natural selection is the difference in mortality (death rates) and fertility (birth rates) between different genetic types. The interplay of the expressed phenotype and the environment influences natural selection. If the phenotype is favorable, the individual survives and perpetuates his or her genetic profile in the gene pool. Genetic drift is a process by which the frequencies of specific alleles change, by chance, within a population.

Each gene pool accounts for all of the alleles for all of the traits of the members of a population. Within a population, different alleles will occur at different frequencies. For instance, approximately 44% of the population has type O blood, 42% of the population has type A blood, 10% of the population has type B blood, and 4% of the population has type AB blood. The percentages of each blood type are directly related to the frequency of each blood type allele. The more frequent the A-allele, the more frequent type A blood would be seen in the population.

The gene frequency of an allele is equal to the number of times the allele occurs compared to the total number of alleles for that trait.

Gene frequency equals the number of a specific type of allele, or the total number of alleles in the gene pool.

DNA changes and genetic disorders

Genetic disorders are caused by changes in the DNA sequence. In general, there is a non-disease-causing allele and a disease-causing allele. Some genetic disorders arise by sporadic mutations in the DNA sequence. Others are inherited from one or both of the parents.

There are several different inheritance patterns associated with genetic disorders. Autosomal dominant and autosomal recessive are two of the most common. Chromosomes come in pairs, one from the egg and one from the sperm. Autosomal dominant disorders require that a person inherit only one disease-causing allele in order to be affected. Even though the corresponding gene on the other chromosome in the pair may be the non-disease-causing allele, having one disease-causing allele is enough to cause the disorder to be present. Autosomal recessive disorders require that a person inherit two disease-causing alleles, one on each chromosome of the

pair, for the individual to be affected. If a person inherits only one disease-causing allele of a recessive disorder they are called a carrier. Carriers are not affected by disease; however, they carry the possibility of passing that disease on to a future child.

Hardy-Weinberg equilibrium

The frequency of disease-causing and non-disease-causing alleles along with the frequency of affected individuals, carriers, and unaffected individuals are related within a mathematical equation known as the Hardy-Weinberg equation.

The equation itself is written as $p^2 + 2pq + q^2 = 1$. For autosomal recessive disorders, p^2 represents the people within the population that have two non-disease-causing alleles (unaffected), $2pq$ represents the people within the population with one disease-causing allele and one non-disease-causing allele (carriers), and q^2 represents the people within the population that have two disease-causing alleles (affected). Because the Hardy-Weinberg equation deals with allele frequencies, the equation $p + q = 1$ may also be used. In this case, p represents the frequency of the non-disease-causing allele within the population, and q represents the frequency of the disease-causing allele within the population.

The Hardy-Weinberg equation is based on the work of Drs. Hardy and Weinberg. Independently, they suggested that there should exist an equilibrium, or balance, between different allele frequencies. They devised a list of conditions that must be true for this balance, known as the Hardy-Weinberg equilibrium, to occur. These include the following:

- No evolutionary forces are acting upon the population.
- The population is “infinitely” large (meaning it is so large that it may be assumed to be infinitely large).
- Individuals have two copies of each gene.
- There is random mating between individuals within the group.
- The frequencies of the alleles are the same in both males and females.
- Generations are non-overlapping.

The Hardy-Weinberg equation has several applications, including use by population geneticists to study the characteristics of certain populations and use by genetic counselors to calculate recurrence risks for individual families affected by genetic disease.

The future

There are several projects underway in an effort to further understand the gene pool, population genetics,

and the human genome. The Human Genome Diversity Project (HGDP) is an international project that seeks to understand the diversity and unity of the entire human species.

The Human Genome Project, a separate venture from HGDP, made the news in 2000 when scientists announced they had elucidated a working draft of the human genome sequence.

Gene regulatory networks

Gene regulation refers to the mechanisms in place that induce or repress a gene's expression. Gene regulatory networks (GRNs) provide information about the interactions between regulators and potential targets they affect. Mathematical and computational models can help explain gene-to-gene interactions or protein-to-protein interactions.

Description

As scientists have learned more about the human genome, it has become clear that 98.5% of the genome does not appear to code for protein production. Through gathering of high-throughput expression data, researchers could infer the existence and potential of GRNs. Epigenetics addresses the types of changes that occur in gene expression through alterations to chromosomes rather than in the DNA sequence.

GRN computational modeling includes tasks such as:

- Key signal transducers, transcription factors and target genes proven as involved in activation of a targeted cellular program (typically from previous studies).
- Arrangement of known information in a network in which nodes (N) represent molecules, and the edges of the set (E) refer to relationships among molecules.
- Expression of the activation level of each N object in a discrete set of values.
- Defining of nodes as functions of the affecting edges to determine the state at each time instant of N changes.

Gene regulation

A complex process controls gene expression. Gene regulation mechanisms act to induce or repress a gene's expression. These can include structural and chemical changes to genetic material; binding of proteins to specific DNA elements to regulate transcription; or mechanisms that modulate the translation of mRNA. Certain promoters and introns affect regulation of genes. Promoters turn the transcription process on or off. Synthesizing of necessary proteins at the appropriate time guides proper function of cells, and all cells regulate transcription and translation of the cell DNA into proteins. The process at which a gene is turned on to produce RNA and protein is called gene expression. Even outside of genes, plenty of regulatory elements can modify the genes' functions. The regulators can be located far (thousands of millions of bases) away from the genes they affect. Promoters are the genes and genetic elements that regulate genes and are arranged in a linear fashion on chromosomes.

Illustration representing the gene regulatory network (GRN) of the bacterium *Escherichia coli*. The GRN is a network of nucleic acids, transcription factors, and proteins that interact to control gene expression within a cell. It allows a bacterium to respond to its environment, for example by switching on genes to process a new food source. (Equinox Graphics/Science Source)

KEY TERMS

Epigenetics—The study of how behaviors and environmental factors can lead to changes in how genes work. The changes are reversible and do not alter the DNA sequence.

Genotype—An organism's collection of genes, or the chemical composition of its DNA, which gives rise to a phenotype.

Introns—Non-coding sections of genes that are transcribed to precursors of mRNA but are edited out as mRNA matures.

mRNA—The single-stranded RNA molecule that delivers genetic instructions from the nucleus of a cell to the ribosomes, where proteins are made.

Phenotype—The observable traits of an individual, such as height, eye color, and blood type. Genotype contributes to phenotype, along with environmental factors.

Epigenetic mechanisms can regulate gene expression by modifying the chemicals of DNA bases and changing the chromosomal superstructure that packages DNA without directly altering the DNA sequence. Non-coding RNA sequences that play roles in regulating gene expression can be induced by environmental factors. There could be more than 100,000 RNA-only genes that contribute to gene regulation. In fact, researchers discovered in the first decade of the twenty-first century that the human genome contains far fewer genes than expected, and that genes are outnumbered at nearly 100 to 1 by elements that regulate genes.

Gene expression levels of bacteria are likely determined by RNA polymerase that recognizes promoter sequences to initiate transcription. Local genetic context contributes to phenotypic diversity in GRNs, and a single gene can be linked to gene expression patterns in its immediate chromosomal neighborhood.

Uncertainty

GRNs are mostly inferred based on data and are part of a highly complex biological system. Identifying important GRNs relies on study conditions, type and amount of data, experimental design, and the size of the network. Although methods might differ, the resulting inferred GRNs tend to vary little and represent similar biological information. Ensemble approaches rely on heavy computation.

QUESTIONS TO ASK YOUR DOCTOR

- If I did not inherit this disease, how did my genes cause it to develop?
- How can a gene regulatory network help diagnose or treat my condition?
- How do gene regulatory networks lead to better drugs to treat diseases?

Determining the accuracy or quality of an inferred GRN relies on including known interactions and assessing the statistical measures used. For a GRN to be complete in its ability to explain development, it should include the expression of relevant sets of cell type-specific proteins.

Usefulness

Along with other gene networks (transcriptional, protein interaction, and metabolic), GRNs interact with an individual's genotype and environmental factors to determine a phenotype. Each observable phenotype is associated with a GRN specific to that type. The more that can be learned about GRNs, the more molecular interactions can be understood. At the same time, GRNs likely are highly phenotype-specific, and they potentially represent a variety of physical biochemical interactions among genes and gene products related to a phenotype. In fact, GRNs are closer to a phenotype than are genetic or epigenetic markers.

Inferring GRNs is not the end result in their application to managing or preventing disease. Rather, the networks can help solve complex biological and biomedical interactions and problems. Current and potential applications include:

- Serving as maps or blueprints of molecular interactions.
- Capturing valuable biological information about causal interactions between gene products.
- Guiding experimental designs in genomics, including perturbations and interventions.
- Acting as biomarkers for diagnosis, prediction or screening, and prognosis.
- Increasing knowledge about interaction changes across different disease processes by comparing GRNs known to affect specific diseases. This can improve biological and biomedical understanding of phenotypes.

- Improving personalized medicine and drug design by creating connectivity maps based on molecular interaction networks.

Examples

Streptococcus pneumoniae contributes to high morbidity and mortality, yet it is part of the commensal nasopharyngeal flora. Use of synthetically generated GRNs helped to study what causes *S. pneumoniae* to transition from healthy flora to disease-causing pathogens. In a 2020 study, investigators were able to build complex GRNs such as genetic toggle switches into the pneumococcal genome for in vivo study of how gene expression regulation affects the pathogenicity.

Another 2020 study sought to explain how some vertebrate species can regenerate retinal cells after injury. Past research had identified genes that promote retinal regeneration, but not the details of the core GRNs that controlled the reprogramming of the cells. The authors found that treatments targeting GRNs that repress neurogenic competence could lead to the regeneration of retinal cells. With further study, these findings could help in the design of therapies targeted to restoring retinal neurons lost to degenerative disease.

Future

GRNs are poised to serve as critical aspects of the networks that explain gene actions and regulation. As more is learned about GRNs and their effects on disease processes, they are becoming the practical embodiment of systems biology approaches to gene expression. Gathering of more and deeper information through large and comprehensive databases will support understanding and application of holistic model interactions between molecules.

Gene therapy

Gene therapy involves treating a disease by adding, removing, or changing the genetic material in the cells of a patient. The transferred genetic material is typically DNA or RNA. Gene therapy seeks to correct abnormal genes which are not functioning properly. DNA is genetic material that contains the genes that have the instructions for the production of proteins. Proteins are responsible for the structure and all the functions of our body and cells. RNA is the genetic material that carries out the instructions for the production of proteins coded in the DNA.

Gene therapy was initially designed to treat inherited diseases, like cystic fibrosis. It is now being investigated as treatment for cancers, autoimmune-diseases like arthritis, and infectious diseases. Gene therapy can be somatic or germline. Somatic gene therapy involves adding, removing, or changing the genetic material in tissue or cells, which results in the production of a naturally

occurring protein that is lacking or not functioning correctly. Germline gene therapy adds, removes, or changes the genetic material in reproductive cells, or embryos, to correct genetic defects that could be passed on to future generations.

Although gene therapy in humans has advanced rapidly, many questions surround its use. For example, some scientists are concerned that the therapeutic genes themselves may cause disease. Others fear that germline gene therapy may be used to control human development in ways not connected with disease, like intelligence or appearance.

The biological basis of gene therapy

Gene therapy has grown out of the science of genetics or how heredity works. Scientists know that life begins in a cell, the basic building block of all multicellular organisms. Humans, for instance, are made up of trillions of cells, each performing a specific function. Within the cell's nucleus (the center part of a cell that regulates its chemical functions) are pairs of chromosomes. These threadlike structures are made up of a single molecule of DNA (deoxyribonucleic acid), which carries the blueprint of life in the form of codes, or genes, that determine inherited characteristics.

A DNA molecule looks like a spiral ladder. The rungs of this ladder are called base pairs. They are made up of nitrogen molecules and arranged in specific sequences. Millions of these base pairs, or sequences, can make up a single gene, specifically defined as a segment of the chromosome and DNA that contains certain hereditary information. The gene or combination of genes formed by these base pairs ultimately direct an organism's growth and characteristics through the production of certain chemicals, primarily proteins, which carry out

most of the body's chemical functions and biological reactions.

Scientists have long known that pathogenic variants (mutations) in genes present within cells can cause inherited diseases like cystic fibrosis, sickle-cell anemia, and hemophilia. Similarly, errors in the total number of chromosomes can cause conditions such as Down syndrome or Turner syndrome. As the study of genetics advanced, however, scientists learned that an altered genetic sequence can also make people more susceptible to diseases, such as atherosclerosis, cancer, and even schizophrenia. These diseases have a genetic component but are also influenced by environmental factors (such as diet and lifestyle). The objective of gene therapy is to treat diseases by introducing functional genes into the body to alter the cells involved in the disease process by either replacing missing genes or providing copies of functioning genes to replace nonfunctioning ones. The inserted genes can be naturally occurring genes that produce the

desired effect, or they may be genetically engineered (or altered) genes.

Scientists have known how to manipulate a gene's structure in the laboratory since the early 1970s through a process called gene splicing. The process involves removing a fragment of DNA containing the specific genetic sequence desired, then inserting it into the DNA of another gene. The resultant product is called recombinant DNA, and the process is called genetic engineering.

Gene therapy approaches

There are different approaches to gene therapy. Viral and nonviral vectors were the first approaches used. More recently, different CRISPR/Cas techniques have been used.

Viral vectors

Gene therapy traditionally uses what is called a vector to transport the genetic material to the cell's nucleus. In

essence, vectors are molecular delivery trucks. Among the first and most popular vectors developed were viruses, because they invade cells as part of the natural infection process. Viruses can be excellent vectors because they colonize certain cell types and tissues in specific organs. As a result, vectors are chosen according to their attraction to certain cells and areas of the body.

One of the first vectors used was a retrovirus. Because these viruses are easily cloned (artificially reproduced) in the laboratory, scientists have studied them extensively and learned a great deal about their biological action. They have also learned how to remove the genetic information that governs viral replication, thus reducing the chances of infection.

Retroviruses work best in actively dividing cells, but cells in the body are relatively stable and do not divide often. As a result, these cells are used primarily for *ex vivo* (outside the body) manipulation. First, the cells are removed from the patient's body, and the virus or vector carrying the gene is inserted into them. Next, the cells are placed into a nutrient culture, where they grow and replicate. Once enough cells are gathered, they are returned to the body, usually by injection into the bloodstream. Theoretically, as long as these cells survive, they will provide the desired therapy.

Another class of viruses called adenoviruses may also prove to be good gene vectors. These viruses can effectively infect non-dividing cells in the body, where the desired gene product is then expressed naturally. In addition to being a more efficient approach to gene transportation, these viruses, which cause respiratory infections, are more easily purified and made stable than retroviruses, thus resulting in less chance of an unwanted viral infection. However, these viruses live for several days in the body, and some concern surrounds the possibility that the patient will infect others with the viruses through sneezing or coughing. Other viral vectors include influenza viruses, the Sindbis virus, and a herpes virus that infects nerve cells.

Nonviral vectors

Scientists have also researched nonviral vectors. These vectors rely on the natural biological process in which cells gather (uptake) macromolecules. One approach is to use liposomes, globules of fat produced by the body and taken up by cells. Scientists are also investigating the introduction of raw recombinant DNA by injecting it into the bloodstream or placing it on microscopic beads of gold shot into the skin with a "gene-gun." Another possible vector under development is based on dendrimer molecules, which are constructed in the laboratory by combining smaller molecules. They have

been used in manufacturing styrofoam, polyethylene cartons, and plexiglass. In the laboratory, dendrimers have been shown to be able to transport genetic material into human cells. They can also be designed to form an affinity for particular cell membranes by attaching to certain sugars and protein groups.

CRISPR/Cas

CRISPR/Cas is a tool derived from the immune system of bacteria that can be used in gene therapy. It can be used to change an organism's DNA by making a cut in the DNA at a specific location and tricking the body's DNA repair mechanism to make the desired change. A significant amount of research is being done to use CRISPR/Cas to treat genetic diseases such as sickle cell disease and cystic fibrosis. One promising gene therapy approach using CRISPR/Cas is called co-opting regulation bypass repair (CRBR). The CRBR technique inserts a shortened version of the normal gene with a terminator sequence at the end before the mutated version of the gene. The terminator sequence prevents the following mutated gene from being used. The advantage of this technique is that it can be used to repair any type of mutation in the gene and can be used in all types of adult tissues.

Gene therapy using CRISPR/Cas is currently only being used on humans in clinical trials. CRISPR/Cas can be used to treat genetic conditions outside of the body (*ex vivo*) and inside of the body (*in vivo*). For example, CRISPR/Cas was used to treat sickle cell disease *ex vivo*. Sickle cell disease is a genetic disease that causes abnormal red blood cells that can't properly carry oxygen throughout the body. A woman with sickle cell disease was successfully treated by removing cells from her bone marrow, using CRISPR/Cas to edit the DNA of these cells and infusing these repaired cells back into her body. Another clinical trial is testing CRISPR/Cas *in vivo* to treat a genetic cause of blindness called Leber's congenital amaurosis. The CRISPR/Cas components are injected directly into the eye to repair the DNA variation causing the blindness.

History

In the early 1970s, scientists proposed "gene surgery" for treating inherited diseases caused by faulty genes. The idea was to take out the disease-causing gene and surgically implant a gene that functioned properly. Although sound in theory, scientists, then and now, lack the biological knowledge or technical expertise needed to perform such a precise surgery in the human body.

In 1983, a group of scientists from Baylor College of Medicine in Houston, Texas, proposed that gene therapy could one day be a viable approach for treating

Lesch-Nyhan disease, a rare neurological disorder. The scientists conducted experiments in which an enzyme-producing gene (a specific type of protein) for correcting the disease was injected into a group of cells for replication. The scientists theorized that the cells could then be injected into people with Lesch-Nyhan disease, thus correcting the genetic defect that caused the disease.

As the science of genetics advanced throughout the 1980s, gene therapy gained an established foothold in the minds of medical scientists as a promising approach to treatments for specific diseases. One of the major reasons for the growth of gene therapy was scientists' increasing ability to identify the specific genetic malfunctions that caused inherited diseases. Interest grew as further studies of DNA and chromosomes (where genes reside) showed that specific genetic abnormalities in one or more genes occurred in successive generations of certain family members who had diseases including intestinal cancer, manic-depressive disorder, Alzheimer's disease, heart disease, diabetes, and many more. Although the genes may not be the only cause of the disease in all cases, they may make certain individuals more susceptible to developing the disease because of environmental influences, like smoking, pollution, and stress. In fact, some scientists theorize that all diseases may have a genetic component.

On September 14, 1990, a four-year-old girl with a genetic disorder that prevented her body from producing a crucial enzyme became the first person to undergo gene therapy in the United States. Because her body could not produce adenosine deaminase (ADA), she had a weakened immune system, making her extremely susceptible to severe, life-threatening infections. W. French Anderson and colleagues at the National Institutes of Health's Clinical Center in Bethesda, Maryland, took white blood cells (which are crucial to proper immune system functioning) from the girl, inserted ADA-producing genes into them, and then transfused the cells back into her body. Although the young girl continued to show an increased ability to produce ADA, debate arose as to whether the improvement resulted from the gene therapy or from an additional drug treatment she received.

Nevertheless, a new era of gene therapy began as more and more scientists sought to conduct clinical trial (testing in humans) research in this area. In that same year, gene therapy was tested on patients with melanoma (skin cancer). The goal was to help them produce antibodies (disease-fighting substances in the immune system) to battle the cancer.

These experiments have spawned an ever-growing number of attempts at gene therapies designed to perform a variety of functions in the body. For example, a gene

therapy for cystic fibrosis aims to supply a gene that alters cells, enabling them to produce a specific protein to battle the disease. Another approach was used for brain cancer patients, in which the inserted gene was designed to make the cancer cells more likely to respond to drug treatment. Gene therapy for patients who have artery blockage, which can lead to strokes, induces the growth of new blood vessels near clogged arteries, thus promoting improved blood circulation.

Currently, there are a host of new gene therapy agents in clinical trials. In the United States, both nucleic acid-based (*in vivo*) treatments and cell-based (*ex vivo*) treatments are being investigated. Nucleic acid-based gene therapy uses vectors (like viruses) to deliver modified genes to target cells. Cell-based gene therapy techniques remove cells from the patient in order to genetically alter them and then reintroduce them into the patient's body. Currently, gene therapies for the following diseases are being developed: cystic fibrosis (using adenoviral vector), HIV infection (cell-based), malignant melanoma (cell-based), Duchenne muscular dystrophy (cell-based), hemophilia B (cell-based), kidney cancer (cell-based), Gaucher disease (retroviral vector), breast cancer (retroviral vector), and lung cancer (retroviral vector). When a cell or individual is treated using gene therapy, and successful incorporation of engineered genes has occurred, the cell or individual is said to be transgenic.

The medical establishment's contribution to transgenic research has been supported by increased government funding. In 1991, the U.S. government provided \$58 million for gene therapy research, with increases in funding of \$15–40 million dollars per year over the following four years. With fierce competition over the promise of societal benefit in addition to huge profits, large pharmaceutical corporations have moved to the forefront of transgenic research. In an effort to be first in developing new therapies, and armed with billions of dollars of research funds, such corporations are making impressive strides toward making gene therapy a viable reality in the treatment of once-elusive diseases.

Diseases targeted by gene therapy

The potential scope of gene therapy is enormous. More than 4,200 diseases have been identified as resulting directly from abnormal genes, along with countless others that may be partially influenced by a person's genetic makeup. Initial research has concentrated on developing gene therapies for diseases whose genetic origins have been established, and for other diseases that can be cured or ameliorated by substances that genes produce.

The following are examples of potential gene therapies. People who have cystic fibrosis lack a gene needed to produce a salt-regulating protein. This protein regulates the flow of chloride into epithelial cells (the cells that line the inner mucous membranes and outer skin layers), which cover the air passages of the nose and lungs. Without this regulation, patients with cystic fibrosis build up a thick mucus that makes them prone to lung infections. A gene therapy technique to correct this abnormality might employ an adenovirus to transfer a normal copy of what scientists call the cystic fibrosis transmembrane conductance regulator, or *CFTR* gene. The gene is introduced into the patient by spraying it into the nose or lungs.

Familial hypercholesterolemia (FH) is also an inherited disease, resulting in the inability to process cholesterol properly, which leads to high levels of artery-clogging fat in the bloodstream. Patients with FH often have heart attacks and strokes because of blocked arteries. A gene therapy approach used to battle FH is much more intricate than most gene therapies because it involves partial surgical removal of patients' livers (*ex vivo* transgene therapy). Corrected copies of a gene that serves to reduce cholesterol buildup are inserted into the liver sections, which are then transplanted back into the patients.

Gene therapy has also been tested on patients with AIDS. The disease is caused by the human immunodeficiency virus (HIV), which weakens the body's immune system to the point that patients are unable to fight off diseases like pneumonia and cancer. In one approach, genes that produce specific HIV proteins have been altered to stimulate immune system functioning without causing the negative effects that a complete HIV unit has on the immune system. These genes are then injected in the patient's bloodstream. Another approach to treating AIDS is to insert via white blood cells genes that have been genetically engineered to produce a receptor that would attract HIV and reduce its chances of replicating.

Several cancers also have the potential to be treated with gene therapy. A therapy tested for melanoma, or skin cancer, involves introducing a gene with an anticancer protein called tumor necrosis factor (TNF) into test tube samples of the patient's own cancer cells, which are then reintroduced into the patient. In brain cancer, the approach is to insert a specific gene that increases the cancer cells' susceptibility to a common drug used in fighting the disease.

Gaucher disease is an inherited disease caused by a mutant gene that inhibits the production of an enzyme called beta-glucocerebrosidase. Patients with Gaucher disease have enlarged livers and spleens, and eventually

their bones deteriorate. Clinical gene therapy trials focus on inserting the gene for producing this enzyme.

Gene therapy is also being considered as an approach to solving a problem associated with a surgical procedure known as balloon angioplasty. In that procedure, a stent (in this case, a type of tubular scaffolding) is used to open the clogged artery. However, in response to the trauma of the stent insertion, the body initiates a natural healing process that produces too many cells in the artery and results in restenosis, or reclosing of the artery. The gene therapy approach to preventing this unwanted side effect is to cover the outside of the stents with a soluble gel that contains vectors for genes that reduce this overactive healing response.

The Human Genome Project

Although great strides have been made in gene therapy in a relatively short time, its potential usefulness has been limited by lack of scientific data concerning the multitude of functions that genes control in the human body. For instance, it is now known that the vast majority of genetic material does not store information for the creation of proteins; rather, it is involved in the control and regulation of gene expression and is therefore much more difficult to interpret. Even so, each individual cell in the body carries 20,000 genes coding for proteins. For gene therapy to advance to its full potential, scientists must discover the biological role of each of these individual genes and where the base pairs that make them up are located on DNA.

To address this issue, the National Institutes of Health initiated the Human Genome Project (HGP) in 1990. Completed in April 2003 and led by James D. Watson (one of the co-discoverers of the chemical makeup of DNA), the HGP provided the map for reading the human genome (a combination of the words *gene* and *chromosomes*). A genome map would clearly identify the location of all genes as well as the more than three billion base pairs that make them up. With a precise knowledge of gene locations and functions, scientists may one day be able to conquer or control diseases that have plagued humanity for centuries.

Scientists participating in the Human Genome Project identified an average of one new gene a day. Their goal was to determine the exact location of all of the genes on human DNA and the exact sequence of the base pairs that make them up. Some of the genes identified through this project include a gene that predisposes people to obesity, one associated with programmed cell death (apoptosis), a gene that guides HIV viral reproduction, and the genes of inherited disorders such as Huntington's disease, Lou Gehrig's disease, and some colon and breast

cancers. In February 2001, scientists published a rough draft of the complete human genome. With fewer than the anticipated number of genes found, around 30,000, the consequences of this announcement were enormous. When the human genome is completed, there will be more information available for gene therapy research and implementation.

The future of gene therapy

Gene therapy seems elegantly simple in its concept: supply the human body with a gene that can correct a biological malfunction that causes a disease. However, there are many obstacles and some distinct questions concerning the viability of gene therapy. For example, viral vectors must be carefully controlled lest they infect the patient with a viral disease. Some vectors, like retroviruses, can also enter cells functioning properly and interfere with the natural biological processes, possibly leading to other diseases. Other viral vectors, like the adenoviruses, are often recognized and destroyed by the immune system, so their therapeutic effects are short-lived. Maintaining gene expression so that it performs its role properly after vector delivery is difficult. As a result, some therapies need to be repeated often to provide long-lasting benefits.

One of the most pressing issues is gene regulation. Genes work in concert to regulate their functioning. In other words, several genes may play a part in turning other genes on and off. For example, certain genes work together to stimulate cell division and growth, but if these are not regulated, the inserted genes could cause tumor formation and cancer. Another difficulty is in learning how to make the gene go into action only when needed. For the best and safest therapeutic effort, a specific gene should turn on, for example, when certain levels of a protein or enzyme are low and must be replaced. But the gene should also remain dormant when not needed, to ensure that it does not oversupply a substance and disturb the body's delicate chemical makeup.

One approach to gene regulation is to attach other genes that detect certain biological activities and then react as a type of automatic off-and-on switch that regulates the activity of the other genes according to biological cues. Although still in the rudimentary stages, researchers are making headway in inhibiting some gene functioning by using a synthetic DNA to block gene transcriptions (the copying of genetic information). This approach may have implications for gene therapy.

Ethical concerns

While gene therapy holds promise as a revolutionary approach to treating disease, ethical concerns over its use

and ramifications have been expressed by scientists and lay people alike. For example, since much needs to be learned about how these genes actually work and their long-term effect, is it ethical to test these therapies on humans, where they could have a disastrous result? As with most clinical trials concerning new therapies, including many drugs, the patients participating in these studies have usually not responded to more established therapies and are often so ill that the novel therapy is their only hope for long-term survival.

Another questionable outgrowth of gene therapy is that scientists could possibly manipulate genes to genetically control traits in human offspring that are not health-related. For example, perhaps a gene could be inserted to ensure that a child would not be bald—a seemingly harmless goal. However, what if genetic manipulation were used to alter skin color or ensure good looks? If a gene is found that can enhance intelligence of children who are not yet born, will everyone in society, the rich and the poor, have access to the technology, or will it be so expensive that only the elite can afford it?

The Human Genome Project, which plays such an integral role for the future of gene therapy, also has social repercussions. If individual genetic codes can be determined, will such information be used against people? For example, will someone who is more susceptible to a disease have to pay higher insurance premiums or be denied health insurance altogether? Will employers discriminate between two potential employees, one with a “healthy” genome, and the other with genetic abnormalities?

Some of these concerns can be traced back to the eugenics movement, which was popular in the first half of the twentieth century. This genetic “philosophy” was a societal movement that encouraged people with “positive” traits to reproduce, while those with less desirable traits were discouraged from having children. Eugenics was used to pass strict immigration laws in the United States, barring less suitable people from entering the country lest they reduce the quality of the country's collective gene pool. Probably the most notorious example of eugenics in action was the rise of Nazism in Germany, which resulted in the Eugenic Sterilization Law of 1933. The law required sterilization for those with certain disabilities and even for some who were simply deemed “ugly.” To ensure that this novel science is not abused, many governments have established organizations specifically for overseeing the development of gene therapy. In the United States, the Food and Drug Administration and the National Institutes of Health require scientists to take a precise series of steps and meet stringent requirements before approving clinical trials.

Gene therapy has been immersed in more controversy and surrounded by more scrutiny in both the health and ethical arena than most other technologies (except, perhaps, for cloning) that promise to substantially change society. Despite the health and ethical questions surrounding gene therapy, the field will continue to grow and is likely to change medicine more quickly than any previous medical advance.

Genetic anthropology

Definition

Genetic anthropology, also known as molecular anthropology, is a branch of science that combines genetic testing with archaeological, linguistic, historical, and cultural information to find out more about humans and learn how they relate to other species.

Description

The field of genetic anthropology was identified in 1962 when Émile Zuckerkandl first introduced the term *molecular anthropology*. The field of genetic anthropology at the time was primarily limited to the study of human evolution and human genetic relationship to other primates.

After that the field expanded, applying genetic information to analyze other subjects such as:

- the history of human populations
- the migration of different populations
- the characterization of DNA in extinct human ancestors
- human variation
- human adaptation to changing environments

Tools used in genetic anthropology

Genetic anthropology initially relied on rudimentary tools such as analyzing proteins. As the field advanced, so did the tools used in genetic anthropology. Genetic anthropologists learned how to use both nuclear and mitochondrial DNA in their research.

Nuclear DNA

Genetic anthropologists study nuclear deoxyribonucleic acid (DNA), the genetic material that contains the instructions for creating proteins. The nuclear DNA is packaged into chromosomes and is found in the control center (nucleus) of each cell of the body, apart from the red blood cells and platelets. All nuclear DNA in a cell, called the nuclear genome, is made up of approximately 3 billion bases. The nuclear genome contains DNA inherited from both parents.

A technician drills a sample of fossilized Neanderthal (*Homo neanderthalensis*) bone. The sample will have its genetic material extracted and sequenced as part of the Neanderthal genome project. Neanderthals were early humans who lived in Europe and the Middle East from 100,000 to 30,000 years ago. (Volker Steger/Science Source)

About 20% of the nuclear genome contains instructions for genes. A gene is a DNA sequence that contains the instructions for proteins. Ninety percent of the genome consists of DNA that does not have instructions for protein. This part of the nuclear genome includes repeated DNA sequences, some of which are found throughout the genome and some of which are clustered together. These repeated sequences are particularly important for the study of evolution and the relationship of humans to primates in the field of genetic anthropology.

Mitochondrial DNA

Genetic anthropologists also study mitochondrial DNA, structures found in the cell (organelles) surrounded by two layers of membrane. Mitochondria turn energy from food into energy that powers the cell. They also help the cell produce heat and store calcium, and they help determine which damaged cells need to be destroyed. Mitochondrial DNA (mtDNA) is the DNA found in the mitochondria. Mitochondrial DNA is similar in humans and non-human primates. There are many mitochondria in each cells, and, therefore, many copies of the mtDNA.

Ninety percent of the mitochondrial genome, in contrast to the nuclear genome, contains the instructions for proteins. The mitochondrial genome contains approximately 37 genes. These genes produce proteins that help the mitochondria function. There are few repetitive sequences in the mitochondrial genome.

MtDNA is only passed from a mother to her offspring through her egg; the fetus inherits an identical copy of the mother's mtDNA. Therefore, mtDNA offers a great vehicle for examining the history of various human populations and their migrations.

Research areas

The origin of modern humans

Two different models have been proposed for the origin of modern humans. One proposes that a single ancestor, *homo erectus*, gave rise to all modern humans. If this theory is correct, then the DNA of modern human individuals would be consistent and similar. Another theory is that modern humans derive from a single population from Africa. If this theory is correct, then

KEY TERMS

Cell—Building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle, and connective tissue.

Chromosome—The package of DNA found in each cell of the human body apart from the red blood cells. Humans have 22 pairs of autosomes (1 to 22) and one pair of sex chromosomes (XY). Females have two X chromosomes, and males have an X and Y. Normally, humans inherit one chromosome of each pair from their mother and one from their father.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T), and cytosine (C). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The order of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid.

Gene—The sequence of bases in DNA or RNA that encodes instructions for a gene product, which is either RNA or a protein.

Genome—The complete set of genetic instructions of an organism.

Hemoglobin—A protein found in the blood that transports oxygen from the lungs to the rest of the body.

Mitochondria—Structures found in the cell (organelles) surrounded by two layers of membrane. Mitochondria turn energy from food into energy that powers the cell. They also help the cell produce heat, store calcium, and choose which damaged cells need to be destroyed.

Mitochondrial mutation—Variation in the mitochondrial DNA that can affect how well the mitochondria function.

Nuclear DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins. The nuclear DNA is packaged into chromosomes and is found in the control center (nucleus) of the cell.

Nuclear genome—The complete set of nuclear DNA found in the nucleus of the cell.

presumably only African populations would have significant genetic variation.

To study which theory is more likely correct, genetic anthropologists analyzed mitochondrial DNA from Africans, Asians, and Europeans. This research supported the theory that modern humans descend from a single population in Africa since modern human genetic variation is generally small, and African populations exhibit the largest degree of genetic variation.

Evolution of humans and apes

Genetic anthropology has been used to study the evolution and similarities between humans and apes. For example, genetic anthropologists have used DNA sequencing to determine that chimpanzees are more closely related to humans than gorillas or orangutans. DNA sequencing of these species has also revealed that humans and chimpanzees diverged only about 5 million years ago.

Human adaptation to altitude

Genetic anthropologists have studied how people living in the mountainous regions of Tibet adapted to living in high altitude. Unlike visitors, who often get altitude sickness and

have higher levels of hemoglobin (a protein found in the blood that transports oxygen to the different parts of the body), mountain dwellers have adapted to low levels of oxygen without increased hemoglobin.

In one study, 1,000 women from this region were examined. Anthropologists conducted interviews, obtained family histories and collected blood and saliva samples. They found that normal hemoglobin concentrations increased the chances of a successful pregnancy. This advantage, acting over many generations, suggests how this group adapted to high altitude.

Factors contributing to high blood pressure

Researchers have studied the sociocultural and genetic factors that affect high blood pressure in African American adults. Certain genetic variants combined with exposure to racism appeared to increase the risk of high blood pressure in this population.

Genetic anthropology and tuberculosis

Anthropologists have studied the genome of tuberculosis bacteria in skeletons from Peru. Ancient Peruvians are believed to have lived several centuries before they had contact with Europeans. By sequencing the genome of

these bacteria, scientists were able to discover that these Peruvians likely contracted tuberculosis from exposure to seals. This research may foster future discoveries about how diseases mutate and jump from one species to another. It may also produce further insights into this ancient population from Peru.

Genetic counseling

Definition

Genetic counseling is a communication process by which personal genetic risk information is translated into practical information for families. Genetic counselors are commonly health care professionals with specialized training and experience in the areas of medical genetics and counseling. They work as members of a health care team, providing individuals and families with information on the nature, inheritance, and implications of genetic disorders to help them make informed medical and personal decisions.

Purpose

Specifically, the process of genetic counseling assists families by:

- Helping families understand information about birth defects or genetic disorders. This includes explaining patterns of inheritance, recurrence risks, the natural history of diseases, and genetic testing options.
- Providing nondirective supportive counseling regarding emotional issues related to a diagnosis or testing options.
- Helping individuals or families make decisions that they are comfortable with, based on their personal, ethical, and religious standards.
- Connecting families with appropriate resources, such as support groups or specific types of medical clinics, locally and nationally.

As of 2021, more than 50 universities offered genetic counseling study programs in the United States and Canada, meeting the rigorous accreditation criteria established by the American Board of Genetic Counseling (ABGC). Most genetic counseling programs are two-year programs that include course work, clinical rotations, and an independent research project. Most applicants enter the field from a variety of disciplines, including biology, genetics, psychology, and nursing.

Types of genetic counseling

Genetic counselors work with people who are concerned about the risk of an inherited disease. These patients represent several different patient populations. Prenatal genetic counseling is provided to couples who have an increased risk for birth defects or inherited conditions and are expecting a child or planning a pregnancy. Pediatric genetic counseling is provided to families with children suspected of having a genetic disorder or with children previously diagnosed with a genetic disorder. Adult genetic counseling is provided to adults with clinical features of an inherited disease or a family history of

one. Cancer genetic counseling is provided to those with a strong family history of certain types of cancer.

Prenatal genetic counseling

There are several different reasons a person or couple may seek prenatal genetic counseling. If a woman is age 35 or older and pregnant, there is an increased chance that the fetus may have a change in the number of chromosomes present. Changes in chromosome number may lead to intellectual disability and birth defects. Down syndrome is the most common change in chromosome number that occurs more often in the fetuses of older women. Couples may seek prenatal genetic counseling because of abnormal results of screening tests performed during pregnancy. A blood test called the alpha fetal protein (AFP) test is offered to all pregnant women. It tests for Down syndrome, open spine defects (spina bifida), and trisomy 18, a type of intellectual disability caused by a change in chromosome number. When this test yields abnormal results, further tests are offered in order to obtain more information about the chance of these conditions in the fetus.

Another reason that people seek prenatal genetic counseling is a family history of birth defects or inherited diseases. In some cases, blood tests of the parents may be available to indicate whether their children would be at risk of being affected. Genetic counselors assess risk in each case, help patients understand their risks, and explore how patients feel about or cope with these risks.

Prenatal tests that are offered during genetic counseling include level II ultrasounds, maternal serum AFP screening, chorionic villus sampling (CVS), and amniocentesis. Level II ultrasound is a detailed ultrasound surveying fetal anatomy for birth defects. Ultrasound is limited to detection of structural changes in anatomy and cannot detect changes in chromosome number. The maternal serum AFP screening is used to indicate whether a pregnant woman has a higher or lower chance of certain birth defects. This test can only determine the chances for a birth defect. The screening cannot diagnose a birth defect. CVS is a way to learn how many chromosomes are present in a fetus. A small piece of placental tissue is obtained for these studies during the 10th to 12th weeks of pregnancy. Amniocentesis is another way to learn how many chromosomes are present in a fetus. Amniotic fluid is obtained for these studies, usually between 16 and 18 weeks of pregnancy. There is a small risk for miscarriage with each of these tests.

Genetic counseling regarding these procedures involves the careful explanation of benefits and limitations of each testing option. The counselor also tries to explore how patients feel about prenatal testing and the

impact of such testing on the pregnancy. Genetic counselors are supportive of any decision a patient makes about whether to have prenatal tests performed.

Pediatric genetic counseling

Families or pediatricians seek genetic counseling when a child has features of an inherited condition. Any child who is born with more than one birth defect, intellectual disability, or dysmorphic features has an increased chance of having a genetic syndrome. One common type of intellectual disability in males for which genetic testing is available is fragile X syndrome. Genetic testing is also available for many other childhood illnesses, such as hemophilia and muscular dystrophy.

Genetic counselors work with medical geneticists to determine whether a genetic syndrome is present. This process includes a careful examination of family history, medical history of the child, review of pertinent medical records in the family, a physical examination of the child, and sometimes blood work or other diagnostic tests. If a diagnosis is made, then the medical geneticist and genetic counselor review what is known about the inheritance of the condition, the natural history of the condition, treatment options, further examinations that may be needed for health problems that are common in the diagnosed syndrome, and resources for helping the family.

The genetic counselor also helps the family adjust to the diagnosis by offering emotional support and counseling. Many families are devastated by receiving a diagnosis, by learning of the likely outcome for the child, and by the loss of the hoped-for healthy child. There would also be a discussion about recurrence risks in the family and who else in the family may be at risk.

Adult genetic counseling

Adults seek genetic counseling when a person in the family decides to be tested for a known genetic condition in the family, when an adult begins exhibiting symptoms of an inherited condition, or when there is a new diagnosis of someone with an adult-onset disorder in the family. In addition, sometimes the birth of a child with obvious features of a genetic disease leads to diagnosis of a parent who is affected more mildly. Genetic counseling for adults may lead to the consideration of presymptomatic genetic testing. Testing a person to determine whether they will be symptomatic for a condition before the symptoms occur is an area of controversy. Huntington's disease, a neurological disease resulting in dementia, is an example of a genetic disease for which presymptomatic testing is available. Onset of the condition occurs between 30 to 50 years of age. Huntington's disease is inherited in an autosomal dominant pattern. If a person has a parent with

QUESTIONS TO ASK YOUR DOCTOR

- Do health insurance policies normally pay for genetic counseling sessions?
- How can I be sure that the information I provide a genetic counselor will remain private and not be given to some other organization or individual?
- Should I share the information I receive from a genetic counselor with other members of my family?
- Will a genetic counselor make recommendations about possible steps to take in case our unborn child is at risk for certain genetic disorders?

the disease, their risk of being affected is 50%. Genetic counselors help patients sort through their feelings about such testing and whether the results would be helpful to them or cause anxiety.

Cancer genetic counseling

A family history of early-onset breast, ovarian, or colon cancer in multiple generations of a family is a common reason a person would seek a genetic counselor who works with cancer patients. While most cancer is not inherited, there are some families among whom a dominant gene is present and causing the disease. The genetic counselor can discuss with a patient the chance that the cancer in the family is related to a dominantly inherited gene. The counselor can also discuss the option of testing for the breast and ovarian cancer genes, *BRCA1* and *BRCA2*. In some cases, the person seeking testing has already had cancer, and in others they have not. Therefore, presymptomatic testing is also an issue in cancer genetics. Emotional support is important for these patients, as they have often lost close relatives from cancer and are fearful of their own risks. For families where a dominant form of cancer is detected through genetic testing, a plan for increased surveillance for the disease can be made.

The pedigree

In all types of genetic counseling, one important aspect of the genetic counseling session is information-gathering about family and medical history. Information-gathering is performed by drawing a chart called a pedigree, which is made of symbols and lines that represent the family history. To accurately assess the risk of inherited diseases, information about three generations of the family, including health status and/or cause of

death, is usually needed. If the family history is complicated, information from more distant relatives may be helpful, and medical records may be requested for any family members who have had a genetic disorder. Through an examination of the family history, a counselor may be able to discuss the probability of future occurrence of genetic disorders.

Ethnicity

In taking a family history, a genetic counselor asks for the patient's ethnicity or ancestral origin. There are some ethnic groups that have a higher chance of being carriers of specific genetic diseases. For instance, the chance that an African American is a carrier of a gene for sickle cell disease is one in 10 individuals. People of Jewish ancestry are more likely to be carriers of several conditions, including Tay–Sachs disease, Canavan disease, and cystic fibrosis. People of Mediterranean ancestry are more likely to be carriers of a type of anemia called thalassemia. Genetic counselors discuss inheritance patterns of these diseases, carrier risks, and genetic screening or testing options.

Consanguinity

Another question that a genetic counselor asks in taking a family history is whether the couple are related to one another by blood. The practice of marrying or having children with relatives is infrequent in the United States, but is more common in some countries. When two people are related by blood, there is an increased chance for their children to be affected with conditions inherited in a recessive pattern. In recessive inheritance, each parent of a child affected with a disease carries a single gene for the disease. The child gets two copies, one from each parent, and is affected. People who have a common ancestor are more likely than unrelated people to be carriers of genes for the same recessively inherited genes. Depending on family history and ethnic background, blood tests can be offered to couples to obtain more information about the chance for these conditions to occur.

Exposures during pregnancy

During prenatal genetic counseling, the counselor will ask about pregnancy history. If the patient has taken a medication or has had a harmful exposure (like radiation), the genetic counselor can discuss the possibility of harmful effects. Ultrasound is often a useful tool to look for some effects of exposures.

Ethical issues

Prenatal diagnosis of anomalies or chromosomal abnormalities leads to a decision about whether a couple

wishes to continue a pregnancy. Some couples chose to continue a pregnancy despite knowledge of a chromosomal abnormality. Prenatal diagnosis gives them additional time to prepare emotionally for the birth of the child and to gather resources. Others choose not to continue a pregnancy in which problems have been diagnosed. These couples have unique emotional needs. Often, the child is very much a desired addition to the family, and parents are devastated that he or she is not healthy. Presymptomatic testing for adult-onset disorders and cancer raises difficult issues regarding the need to know and the reality of dealing with abnormal results before signs of symptoms. The National Society of Genetic Counselors (NSGC) has established a code of ethics to guide genetic counselors in caring for patients. The NSGC Code of Ethics is based on four ethical principles:

- Beneficence is the promotion of personal well-being in others. The genetic counselor is an advocate for the patient.
- Nonmaleficence is the ethic of doing no harm to a patient.
- Autonomy is recognizing the value of the individual, the person's abilities, and their point of view. Important aspects of autonomy are truthfulness with patients, respecting confidentiality, and practicing informed consent.
- Justice is providing equal care for all, freedom of choice, and providing a high quality of care.

Informed consent applies to ensuring that patients fully understand the risks, benefits, and limitations of medical testing or procedures. For genetic testing and counseling, informed consent ensures that the patient fully understands the test or procedure, its benefits and limitations, and possible outcomes. Counselors and other professionals must make patients aware of possible negative outcomes as well as positive ones. Genetic counselors have the knowledge and skills to provide the appropriate information and support to patients for informed consent.

Perhaps the main ethical principle of genetic counseling is the attempt to provide nondirective counseling. This requires a patient-centered approach by providing care focused on the thoughts and feelings of the patient. New genetic tests and the transition to genomic tests, which involve multiple genes, have complicated the ethics and liability associated with genetics. Genetic counselors can help patients navigate through the unfamiliar territory of genetic testing.

Legal and social issues

Legal issues associated with the relatively new world of genetics in medicine, such as regulation of tests and

intellectual property, are broad issues for policymakers to address. Some ethical issues cross into important legal and social issues as part of genetic testing. Protecting patient health information is central to the Health Insurance Portability and Accountability Act (HIPAA), which makes all health information confidential. Genetic counselors must obtain permission from a patient in order to share test results or genetic diagnoses even before informing other family members who might be affected. Other legal and social issues associated with genetic counseling include:

- Coverage of genetic testing by insurance companies and how it might affect decisions.
- Avoiding genetic discrimination, and concerns about discrimination, that might affect patient testing decisions.
- Legal requirements or litigation involving informed consent and patient privacy.
- Liability issues related to failing to test a person.
- Failing to properly communicate test results or share them with the appropriate health providers, causing legal liability.
- Liability from over-testing or choice of tests.
- Gene editing and broad ethical and social concerns surrounding altering genes, as well as the benefits.

Genetic disorders

Definition

A genetic disorder is a disease or other health problem caused by an abnormality in a person's genome. Variations within the DNA sequence of a particular gene affect its function and may cause or predispose an individual to a particular disease. Alterations in the genome may increase the frequency of disorder and disease within entire populations.

Description

Although there are many types of genetic disorders, a specific disorder does not have to be heritable to have a genetic basis. For example, non-heritable disorders can also arise from mutations in somatic cells resulting from exposure to mutagenic factors in the environment. Mutations, whether inherited mutations that appear in every cell of the body or random mutations affecting a particular cell, can cause groups of cells to grow out of control, or inhibit the processes (contact inhibition processes) that normally prevent this from happening.

Some diseases and disorders are traced from the presence of a single form of a gene to a mutation in a specific normal gene. Other common conditions, including not only some cancers but also some forms of heart disease and diabetes, are polygenic. Variations in a number of genes, in combination with environmental conditions that determine the extent to which these genes are expressed, affect the risk that an individual will develop such conditions. The risk calculations associated with many of the disorders commonly regarded as genetic diseases are often predictable as functions of relatively simple Mendelian inheritance.

There are many types of genetic diseases and disorders resulting from a few well-established mechanisms. Autosomal dominant disorders, in which one deleterious gene or allele expresses itself over a normal complementary allele, is the mechanism underlying Crouzon disease. In contrast, phenylketonuria is an autosomal recessive disorder in which both harmful alleles must be present. There are also sex-linked diseases and disorders wherein the deleterious gene or genes lie on sex chromosomes (X and Y chromosomes). There are X-linked dominant disorders (e.g., hypoplastic amelogenesis imperfecta), X-linked recessive disorders (Menkes syndrome), and Y-linked disorders, in which the only mechanism of transmission is from father to son.

Not all genetic disorders depend on alterations to nuclear DNA. There are disorders, such as mitochondrial myopathy, that can result from alterations to mitochondrial DNA.

Genetic counseling deals with the problems associated with the diagnosis of a genetic disorder, the probable disease course, and possible treatments and management. Genetic testing is used to assess the risks of genetic disorders and the risks of recurrence. Options for dealing with the risk of a genetic disorder and its recurrence sometimes involve methods of contraception, adoption, insemination by donor sperm, and prenatal diagnosis.

Bayes' theorem is used in genetic epidemiology in order to obtain the probability of disease in a group of people with some characteristic. In addition, Bayes' theorem is able to calculate unknown conditional probabilities (PVP) from known conditional probabilities (detection rate or sensitivity). For example, biochemical and ultrasound marker-based screening use a derivation of Bayes' theorem to select patients for whom further testing for a particular disease or disorder may be appropriate.

A variation of Bayes' theorem, termed the Bart's test, is very popular in the prenatal screening projects. Bart's test allows an adjustment of the probability of the disease (expressed as 1/total) for an appropriate factor

named likelihood ratio, that is, the ratio between the detection rate and the false positive rate.

Except for genes appearing on the X or Y chromosomes in males, there are usually two copies of each gene in humans. This redundancy provides a buffer to genetic diseases and disorders. In many cases, only one correctly functioning copy of a gene is necessary. Only when an individual has obtained two copies of an abnormal recessive gene will the corresponding disease manifest itself. Inheritance of this type is called homozygous recessive.

A heterozygous individual with one allele for such a condition may be completely unaffected. In other cases, the individual may even be at an advantage, which provides a clue as to why the mutation remains in the population. Sickle cell disease, relatively common among people of African descent, is an often-fatal condition in which red blood cells become sickle-shaped when the oxygen content of the blood decreases, as it does during physical exertion. The deformed blood cells block small blood vessels, causing tissue death (necrosis) in affected areas. Although only an individual with two alleles for sickle cell will have the disease, individuals with one sickle cell allele (type pf gene) have sickle cell trait. Trait carriers only experience disease-like symptoms at extreme low-oxygen conditions such as those found at very high altitudes. On the other hand, such an individual actually gains a significant advantage relative to malarial resistance. Malaria is endemic in Africa, and the evolutionary benefit of having a large population of people who are heterozygous for the trait overcomes the disadvantage of a fatal condition affecting homozygotes with two copies of the allele. Therefore, this type of genetic disease may persist at a relatively high frequency in a population over a long period of time, even if the actual disorder is serious or potentially fatal.

With dominant alleles, one copy of a defective gene is enough to produce a disease or disorder. Genetic disorders with dominant inheritance that are lethal at an early age do not remain in the population because they kill the affected individual before he or she can reproduce. However, nonlethal dominant genetic disorders, such as the hand and foot malformation called camptobrachydactyly, do persist over time. Likewise, a lethal genetic disorder such as Huntington's disease that strikes after the individual has reached reproductive maturity can also be passed along to future generations.

If the gene associated with a disorder is found on the X chromosome, typically males are afflicted more often and/or more severely than females. That is because in females who are heterozygous for such an X-linked trait, there is a normal version of the gene to compensate. Males have only one X chromosome, so if an X-linked gene is mutated, it usually has a severe effect. X-linked genetic disorders include hemophilia and red-green color blindness.

Chromosome abnormalities, such as the addition or deletion of a chromosome, may result from errors that occur when gametes (sperm and egg) are formed, during fertilization, or during the early development of the zygote. Most chromosome aberrations are lethal, resulting in spontaneous abortion (miscarriage), or death in infancy. Only a few, including the extra copy of chromosome 21 that results in Down syndrome, produce individuals who, although affected by mental and physical abnormalities, can survive into adulthood.

Genetic gain

Definition

Genetic gain is a measure of achieved increase in desirable traits (characteristics) of an organism or

KEY TERMS

Carrier—Individual who has a pathogenic variant (mutation) in one copy of a gene that causes an autosomal recessive condition. Carriers often do not have symptoms. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T), and cytosine (C). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The order of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid.

Gene—A unit of information on DNA that contains the instructions for making a protein.

Genetic marker—A DNA or RNA sequence variant. In plant breeding, markers can be linked to particular plant characteristic (traits).

Genome—The complete set of genetic instructions of an organism.

Genomic selection—A method in plant breeding that predicts the value of breeding stock based on genetic information.

Host—The body that the virus has infected.

Mutation rate—A measure of how often the virus makes errors when copying itself.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Protein—The building blocks for life that guide the development and functioning of the virus.

Recessive disease—Condition caused by a pathogenic variant (mutation) in both copies of a particular gene. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

Replication—The process by which the virus makes copies of itself.

RNA (ribonucleic acid)—The genetic material that is involved in creating proteins.

Variant—Change in the sequence of a genome.

population as a result of genetic changes. Genetic gain is a key concept in the fields of quantitative genetics and breeding. Genetic gain is sometimes called gain-of-function when referring to increases in disease-causing capabilities of organisms accomplished in medical research.

Description

Genetic gain made through breeding programs improves crop yield and animal production. Genetic gain in microorganisms such as viruses results from variants that make the microorganisms more infectious or more deadly, which is useful in creating vaccines, treatments, and in biodefense research.

Genetic gain can happen naturally in the wild as the result of the increased survival of organisms with desirable genetic variants. It can also happen in the laboratory through selection of organisms with certain genetic traits or through the modification of the genome of the organism. Programs to increase genetic gain in food production work to insure that they are not resulting in too much inbreeding. Inbreeding decreases genetic variation and increases the likelihood of a recessive genetic disease. A

recessive disease develops when an offspring has a pathogenic variation in both copies of a particular gene. Offspring with a recessive disease have inherited a pathogenic variant from each carrier parent.

Genetic gain in agriculture

Genetic gain is an objective of crop breeding. Breeders seek to increase the frequency of genetic variants that increase the traits (characteristics) of interest such as disease resistance and increased yield. The factors that make it easier to achieve genetic gain for a particular trait in a particular crop include the following:

- the large role of genetics in the trait of interest
- a shorter breeding cycle
- a high degree of genetic variation
- plant stock available for breeding with the desired traits

Conventional breeding programs that increase genetic gain in agriculture are labor intensive and can take decades to complete. They involve breeding parent plants that have a high degree of variability and selecting plants for further breeding based on desirable traits.

Newer techniques use genetic markers to select plants that will be part of a breeding program. Genetic markers are DNA sequence variants that are linked to a particular plant trait or traits. Genome selection estimates the genetic worth of a plant based on analysis of a large number of genetic markers from the whole genome. Plants with higher genetic worth are more likely to contribute to genetic gain and are more valuable in breeding programs. Genetically modified crops increase genomic gain by artificially modifying the genome of the organism for better performance.

Genetic gain in infectious disease

Genetic gain can happen when viruses make copies of themselves (replicate) in order to infect a host. During replication, viruses need to make a copy of their genome. Errors can sometimes happen during replication, resulting in a new variant in the genome. Viruses with higher mutation rates are more likely to have genetic gain.

Some variants are significant enough to become dominant and increase genetic gain in the population. Variants that are more infectious or are more resistant to vaccines often become dominant because they can surpass other variants. For example, during the COVID-19 pandemic, the Alpha variant (UK) and the Delta variant (India) spread more quickly than the original virus because they were 50% to 60% more transmissible. These variants became dominant and increased the genetic gain of the virus. The potential for genetic gain also increases when the number increases of people infected with a virus. More infected people means more replication and increased likelihood of new variants.

Analyzing genetic gain in microorganisms such as viruses can help researchers study how viruses become more infectious and deadly. This type of research can involve creating genetically modified viruses with different variants in the laboratory. This activity allows researchers to improve management of viruses in the community and modify vaccines and treatments so that they work on viruses even as they evolve. This research is controversial, however, because it runs the risk that more lethal strains could mistakenly be released into the environment.

Genetic Information Nondiscrimination Act (GINA)

Definition

The Genetic Information Nondiscrimination Act (GINA) of 2008 is a U.S. federal law that prevents discrimination in health insurance and employment based on an individual's genetic information or genetic profile.

Purpose

Genetic information is fast becoming a cornerstone of modern medicine. The use of genetic testing and genetic information for diagnosing disease and predicting susceptibility to conditions ranging from cancer to Alzheimer's disease to mental illness has increased dramatically, as has the amount of genetic information about individuals that can be obtained or bought. In 2014, approximately 700,000 Americans had their DNA sequenced, at least in part, at a cost of less than \$1,000 for a complete genome sequence. Genetic information can help people identify and understand inherited medical conditions that run in their families and their risk of having a child with a genetic disorder, as well as their risk of developing certain health conditions. This information can enable people to make lifestyle choices that may reduce their risk for certain conditions, as well as help them make important decisions about their medical care. However, the availability of genetic information leaves people increasingly vulnerable to discrimination and stigmatization based on genetic makeup.

The purpose of GINA is to encourage people to have genetic testing as an important part of their health care, without fear that the results could be used against them. Many people avoid genetic testing or revealing family medical histories that might improve their health care out of fear of genetic discrimination. For example, if genetic testing reveals a gene mutation that causes an inherited or other disorder, or increases the risk of developing a serious disease, employers might not hire or promote those people, or might even fire them. Before the enactment of the Affordable Care Act of 2010 (ACA or "Obamacare"), companies could deny people health insurance or charge them very high premiums based on their genetic information. GINA is intended to encourage people to have recommended genetic tests, as well as to feel comfortable about discussing their family medical histories, both with other family members and with healthcare providers. GINA is also intended to encourage people to volunteer for medical research and clinical trials of new tests, drugs, and therapies without fear of genetic discrimination.

The following are typical examples of genetic discrimination that GINA was designed to prevent:

- A child with a gene for a rare genetic disorder that could be controlled with therapy was denied coverage under her parents' health insurance policy, even after her state passed a law prohibiting genetic discrimination.
- A man's health insurance premiums skyrocketed after his mother tested positive for a gene causing a amyotrophic lateral sclerosis (ALS).

- A woman was fired from her job after her mother was diagnosed with familial cancer because the woman had a 50% risk of having inherited the disease.
- A 50-year-old woman was denied a promotion when it became known that early-onset Alzheimer's disease ran in her family.
- A company hoping to defend itself against potential workers' compensation claims administered genetic tests to employees without their consent; employees who refused to undergo testing faced possible dismissal.

Description

Genetic information is defined as information obtained from family medical histories and genetic test results—including test results of embryos and fetuses, and of family members up to fourth-degree relatives—as well as genetic counseling or genetic education requested or received by an individual or family member. Genetic tests are defined as analyses of DNA, RNA, chromosomes, and proteins or metabolites that detect the presence of genes, mutations, or chromosomal changes.

Title I of GINA prohibits genetic discrimination in obtaining health insurance. This means that health insurance providers cannot request, require, purchase, or use genetic information when making decisions about insurance eligibility, coverage, or premiums for individuals or their family members, nor can they require people to undergo genetic testing. Title I became effective on May 21, 2009. It is enforced by the Departments of Labor, Treasury, and Health and Human Services. However, Title I was made largely redundant by the ACA, which prohibits genetic discrimination by insurance providers in both the individual and group health insurance markets.

Title II of GINA prohibits genetic discrimination in employment. This means that employers cannot request, require, or use an individual's genetic information to make decisions about hiring, firing, promotion, pay, job assignments, or certain other terms of employment. In addition to employers, Title II applies to employment agencies, labor organizations, joint labor-management training programs, and apprenticeship programs. It went into effect on November 21, 2009. Title II is under the jurisdiction of the Equal Employment Opportunity Commission (EEOC).

GINA also requires that people participating in clinical research projects be informed of any risks associated with the project and be provided with a description of how the researchers will maintain the confidentiality of any personal genetic information obtained in the study. Health insurers or group health plans engaged in research

KEY TERMS

Affordable Care Act (ACA)—The Patient Protection and Affordable Care Act (“Obamacare”); signed into law by President Barack Obama in March of 2010, the ACA overhauled the U.S. healthcare system.

Equal Employment Opportunity Commission (EEOC)—The U.S. Government agency charged with enforcing Title II of GINA, which covers employment discrimination.

Genetic discrimination—Discrimination against people in employment or health insurance on the basis of their genetic information, including genetic testing results or a family medical history that suggests genetic predisposition to a disease.

Genetic testing—Testing of chromosomes and genes from an individual or unborn baby for a genetic condition. Genetic testing can only be done if the gene is known.

may request, but not require, that their members undergo genetic testing for clinical research.

Origins

The EEOC declared in 1995 that genetic discrimination in employment and other areas was prohibited under the Americans with Disabilities Act (ADA); however, this decision was not legally binding. That same year, Congresswoman Louise Slaughter and Senator Olympia Snow introduced federal legislation that would limit genetic discrimination in health insurance coverage. Their bill failed, as did similar legislation introduced in each successive congressional session. Subsequent introduced bills were expanded to include genetic discrimination in employment as well as health insurance. However, it took 14 years before GINA passed unanimously in the Senate and by 414 to 1 in the House of Representatives. GINA was signed into law by President George W. Bush on May 22, 2008.

Limitations

GINA does not apply to employers with fewer than 15 employees; to health benefits provided to federal employees or military personnel (TRICARE); or to health care provided by the Veterans Health Administration (VHA) or the Indian Health Service. However, these groups are protected by other regulations. The ACA protects against genetic discrimination by private individual and group health insurers. President Bill Clinton

protected federal workers from genetic discrimination by executive order in 2000. The military adopted GINA policies for TRICARE in 2008. The VHA has covered genetic and hereditary conditions since 1990, on the grounds that such conditions could be “service aggravated.” State laws may also protect people from genetic discrimination, although these vary widely. In 1991, Wisconsin became the first state to prohibit discrimination based on genetic tests. Although some state laws are more protective than GINA, most are less protective.

GINA does not prevent health insurers from basing eligibility, coverage, and premiums on an individual’s health or on symptoms, diagnosis, or treatment of a genetic condition, although it does protect against discrimination based on health information about family members. As of January 1, 2014, the ACA prohibited the denying of coverage or the institution of higher premiums based on a person’s health or preexisting conditions, including genetic conditions. Other limitations of GINA remain in effect:

- GINA is not retroactive. It does not apply to discrimination that occurred before the law’s effective dates. However, it does apply to genetic information that was collected prior to the law.
- GINA does not prohibit healthcare providers from recommending genetic tests; nor does it require health insurers to cover specific genetic tests and treatments.
- GINA does permit health insurers to ask for the minimum genetic information necessary for coverage decisions for certain medical tests or treatments. For example, in deciding whether to cover a prophylactic mastectomy (preventive breast removal), the insurer may determine whether a woman has a *BRCA* gene that greatly increases her risk of breast cancer. However, the insurer cannot use this information to discriminate against her.

Most significantly, Title I of GINA applies only to health insurance. It does not protect people from genetic discrimination in other types of insurance coverage, such as life, disability, and long-term-care insurance. As of 2015, California, Oregon, and Vermont were the only states with regulations prohibiting the use of genetic information in determining eligibility, coverage, and premiums for these types of insurance. At least one large insurance company asks prospective customers about genetic testing and informs them that refusal to disclose genetic testing results could cause their application to be denied or result in higher premiums. Other insurers were expected to eventually follow suit. Even companies that do not request genetic information can often find it in applicants’ medical records.

QUESTIONS TO ASK YOUR DOCTOR

- Do you recommend that I have genetic testing?
- What information will genetic testing provide?
- Will my genetic test results be available to my employer or insurance company?
- Could my genetic test results increase my life insurance premiums or prevent me from getting life insurance?
- How will my genetic information be kept confidential?

It appears that many people are declining genetic testing that might improve disease prevention or facilitate early diagnosis and treatment because they fear losing their life, long-term-care, or disability insurance or facing skyrocketing premiums due to test results. A Harvard Medical School study found that people who learned that they carried a gene for early-onset Alzheimer's disease were five times more likely than a control group to buy long-term-care insurance; however, they were very worried about insurance company discrimination if the test results appeared in their medical records. GINA's legislative sponsors recognized the significance of these omissions, but after the 14-year battle to pass GINA they were willing to settle for what they could get. For their part, long-term-care and life insurers argue that they need genetic information from applicants in order to make sound business decisions.

Results

People who believe that they suffered genetic discrimination in the workplace can file charges with the EEOC. As of 2014, the EEOC had received hundreds of claims from employees, former employees, and job applicants charging that companies had asked them for genetic information or used it to discriminate against them. Although many complaints have been dismissed, as of December 2013, the EEOC had filed more than 1,000 charges under GINA. The EEOC settled its first lawsuit for a GINA violation in 2013, and a second class-action lawsuit was pending in federal court as of 2014. Both cases charged employers with asking about family medical histories, such as cancer and mental disorders, during pre-employment medical exams and, in the second case, on an annual basis. In the first lawsuit, a fabrics manufacturer agreed to pay \$50,000 in compensation to a temporary worker who, when offered a permanent job, was asked to disclose her family medical history. Other job applicants at this company were also asked to provide genetic information. In settling the

complaint, the company admitted no wrongdoing but agreed to provide employees in charge of hiring with antidiscrimination training.

A 2015 federal case in Atlanta, Georgia, took GINA in an unexpected direction. Two workers were suspected of leaving feces in a grocery company warehouse. Fearing they would lose their jobs, they agreed to have DNA testing to clear themselves. However, they became the brunt of humiliating jokes and subsequently sued the company. Although the only disclosed genetic information was that the men were not responsible for the acts, the judge ruled that the DNA tests fell under GINA. The jury awarded the workers \$2.2 million.

As of 2015, it was unclear whether GINA was preventing genetic discrimination and alleviating fears among the general public. Concerns over genetic discrimination by life, disability, and long-term-care insurers are increasing with growing awareness of predictive testing for diseases such as Alzheimer's disease and breast and colon cancers. Up to 25% of volunteers in a DNA sequencing study at Harvard dropped out because of insurance concerns. Genetic counselors report that clients frequently express fear over the confidentiality of their genetic test results and ask that the results be kept out of their medical records. This, however, undermines the usefulness of genetic testing. Although some experts believe that such concerns are exaggerated, genetic discrimination can be subtle—people do not necessarily know why they are turned down for insurance coverage.

GINA controversies

Some experts argue that the repercussions of GINA are broader than many employers realize. For example, GINA limits the information that companies can use to assess their workers' fitness and to promote healthy lifestyle choices. Most large U.S. employers sponsor employee wellness programs; however, these programs can ask about family medical histories only with the participant's explicit permission, which may limit their effectiveness. Employers that have mandatory pre-employment physicals or exams can be prohibited from asking for relevant information, which some critics argue is in conflict with good medical practices. Furthermore, company physical exams are the only preventive healthcare that some people receive. Supporters of GINA argue that employers are not in a position to understand or properly utilize genetic information. In the case of the lawsuit against the fabrics manufacturer, the family medical history was requested by a third-party medical provider, but the EEOC says that employers must inform such providers about GINA restrictions.

Some researchers and bioethicists argue that typical patient consent forms do not adequately inform people

about the risk of release, re-identification, and misuse of their genetic information. For example, in 2013, researchers used genealogy websites to readily identify many supposedly anonymous individuals who had their DNA analyzed for research purposes. A Presidential Commission for the Study of Bioethical Issues recommended additional measures to safeguard genetic information. Nevertheless, legions of people are perfectly willing to share their genetic information, posting genetic test results online for anyone to see.

Genetic mapping

Definition

The aim of genetic mapping is to determine the linear sequence of genes in genetic material. The mapping can be performed at several levels of detail (resolution) that fall into two broad types: traditional genetic, or linkage, mapping and more detailed physical mapping.

Description

Linkage mapping shows the relative, rather than absolute, positions of genes along a chromosome and is a technique that has been used since the early 1900s. Early geneticists determined that genes were found on chromosomes. They also reasoned that because the various forms of genes, or alleles, could be precisely exchanged during meiosis through crossovers between homologous chromosomes, the genes for specific characteristics must lie at precise points along each chromosome. It followed that the mapping of chromosomes could, therefore, be made from the observation of crossovers.

Between 1912 and 1915, the American scientist Thomas Hunt Morgan (1866–1945) hypothesized that if genes were arranged linearly along chromosomes, then those genes lying closer together would be separated by crossovers less often than those lying further apart. Genes lying closer together would thus have a greater probability of being passed along as a unit. It follows that the percentage of crossovers would be proportional to the distance between two genes on a chromosome. The percentage crossover can be expressed as the number of crossovers between two genes in meiosis. One genetic map unit (m.u.) is defined as the distance between gene pairs for which one product out of 100 is recombinant (a product of crossover). S recombinant frequency (R.F.) of 0.01 (1%) is defined as 1 m.u., and a map unit is sometimes referred to as a centimorgan (cM) in honor of Thomas Hunt Morgan.

As an example of how linkage mapping might work, suppose two characteristics, A and B, show a 26% crossover. Assign 26 crossover units to the distance between these two genes. If a characteristic C turns out in breeding experiments to have 9% crossover with B and 17% crossover with A, it would then be located between A and B at a point 9 units from B and 17 units from A. Compiling the information from many such breeding experiments creates a chromosome map that indicates the relative positions of the genes that code for certain characteristics. Accordingly, the further apart any two genes are on the same chromosome, the greater the incidence of crossing over between them.

A linkage map is limited because recombination frequencies can be distorted relative to the physical distance between sites. As a result, the linkage map is not always the best possible representation of genetic material.

While linkage maps only indicate relative positions of genes, physical maps are more accurate and aim to show the actual number of nucleotides between each gene. Restriction maps are constructed by cleaving DNA into fragments with restriction enzymes. These enzymes recognize specific short DNA sequences and cut the duplex. The distances between the sites of cleavage are then measured. The positions of the target restriction sites for these enzymes along the chromosome can be used as DNA markers. Restriction sites generally exist in the same positions on homologous chromosomes, so the positions of these target sites can be used rather like milestones along a road and can act as reference points for locating significant features in the chromosome.

A map of the positions of restriction sites can be made for a localized region of a chromosome. It is made by comparing the sizes of single enzyme breakages (digests) of the region of interest with double digests of the same region. This means that two different restriction enzymes are applied, one to each of two separate chromosome extracts of the region of interest, and subsequently the two enzymes are used together in a third digestion with the chromosome extract. The chromosome fragments resulting from the three digestions are then subjected to a biochemical procedure known as gel electrophoresis, which separates them and gives an estimation of their size. Comparison of the sizes of the chromosome fragments resulting from single and double restriction enzyme digestions allows for an approximate location of the target restriction sites. Thus, such maps represent linear sequences of restriction sites. As this procedure determines the sizes of digested chromosome fragments, the distances between sites in terms of the length of DNA can be calculated, because the size of a fragment estimated from an electrophoresis experiment is proportional to the number of base pairs in that fragment.

A restriction map does not intrinsically identify sites of genetic interest. For it to be of practical use, mutations have to be characterized in terms of their effects upon the restriction sites. In the 1980s, it was shown how restriction fragment length polymorphisms (RFLPs) could be used to map human disease genes. RFLPs are inherited by Mendelian segregation and are distributed in populations as classical examples of common genetic polymorphisms. If such a DNA variant is located close to a defective gene (which cannot be tested directly), the DNA variant can be used as a marker to detect the presence of the disease-causing gene. The prenatal examination of DNA for particular enzyme sites associated with

certain hereditary diseases has proved to be an important method of diagnosis. Clinically useful polymorphic restriction enzyme sites have been detected within the beta-like globin gene cluster. For example, the absence of a recognition site for the restriction enzyme HpaI is frequently associated with the allele for sickle-cell anemia, and this association has been useful in prenatal diagnosis of this disease.

The ultimate genetic map is the complete nucleotide sequence of the DNA in the whole chromosome complement, or genome, of an organism. Several completed genome maps already exist. Simple prokaryotic organisms, such as bacteria, with their relatively small chromosomes of one to two million base pairs, were the first to be mapped. Later, eukaryotic organisms such as the yeast *Saccharomyces cerevisiae* and the nematode worm *Caenorhabditis elegans* were mapped. In 2000, the Human Genome Project produced the first draft of the human genome. The project adopted two methods for mapping the three billion nucleotides. The earlier approach was a “clone by clone” method. In this, the entire genome was cut into fragments up to several thousand base pairs long and inserted into synthetic chromosomes known as bacterial artificial chromosomes (BACs). The subsequent mapping step involved positioning the BACs on the genome’s chromosomes by looking for distinctive marker sequences called sequence tagged sites (STSs), whose location had already been pinpointed. Clones of the BACs are then broken into smaller fragments in a process known as shotgun cloning. Each small fragment was then sequenced and computer algorithms that recognize matching sequence information from overlapping fragments were used to reconstruct the complete sequence inserted into each BAC. It was later argued that the first mapping step was unnecessary and that the algorithms used to reassemble the shotgunned DNA fragments could be applied to cloned random fragments taken directly from the whole genome. In this whole-genome shotgun strategy, fragments were first assembled by algorithms into larger scaffolds and the correct position of these scaffolds on the genome was worked out by STSs. The latter method speeded up the whole procedure considerably, and is currently being used to sequence genomes from other organisms.

Genetic testing

Definition

A genetic test seeks to identify changes in a person's chromosomes, genes, or proteins that are associated with inherited disorders. Genetic testing is performed to determine if a person has or will develop a certain disease or could pass a disease to his or her offspring. Genetic tests also determine whether or not couples are at a higher risk than the general population for having a child affected with a genetic disorder.

Purpose

Some families or ethnic groups have a higher incidence of a certain disease than does the population as a whole. For example, individuals from Eastern European, Ashkenazi Jewish descent are at higher risk for carrying genes for rare conditions that occur much less frequently in populations from other parts of the world. Before having a child, a couple from such a family or ethnic group may want to know if their child would be at risk of having that disease. Genetic testing for this type of purpose is called genetic screening.

During pregnancy, the baby's cells can be studied for certain genetic disorders or chromosomal problems such as Down syndrome. Chromosome testing is most commonly offered when the mother is 35 years or older at the time of delivery. When there is a family medical

history of a genetic disease, or there are individuals in a family affected with developmental and physical delays, genetic testing may also be offered during pregnancy. Genetic testing during pregnancy is called prenatal diagnosis.

Prior to becoming pregnant, couples who are having difficulty conceiving a child or who have had multiple miscarriages may be tested to see whether a genetic cause can be identified.

A genetic disease may be diagnosed at birth by doing a physical evaluation of the baby and observing characteristics of the disorder. Genetic testing can help to confirm the diagnosis made by the physical evaluation. In addition, genetic testing is used routinely on all newborns to screen for certain genetic diseases that can affect a newborn baby's health shortly after birth.

There are several genetic diseases and conditions in which the symptoms do not occur until adulthood. One such example is Huntington's disease. This is a serious disorder affecting the way in which individuals walk, talk, and function on a daily basis. Genetic testing may be able to determine if someone at risk for the disease will in fact develop the disease.

Some genetic defects may make a person more susceptible to certain types of cancer. Testing for these defects can help predict a person's risk. Other types of genetic tests help diagnose, predict, and monitor the course of certain kinds of cancer, particularly leukemia and lymphoma.

Precautions

Because genetic testing is not always accurate, and because there are many concerns surrounding insurance and employment discrimination for the individual receiving a genetic test, genetic counseling should always be performed prior to genetic testing. A genetic counselor is an individual with a master's degree in genetic counseling. A medical geneticist is a physician specializing and board certified in genetics.

A genetic counselor reviews the person's family history and medical records and the reason for the test. The counselor explains the likelihood that the test will detect all possible causes of the disease in question (known as the sensitivity of the test), and the likelihood that the disease will develop if the test is positive (known as the positive predictive value of the test).

Learning about the disease in question, the benefits and risks of both a positive and a negative result, and what treatment choices are available if the result is positive will help prepare the person undergoing testing. During the genetic counseling session, the individual

A scientist performing genetic testing in a laboratory. (Alexander Rath/Shutterstock)

interested in genetic testing will be asked to consider how the test results will affect his or her life, family, and future decisions.

After this discussion, the person should have the opportunity to indicate in writing that he or she gave informed consent to have the test performed, verifying that the counselor provided complete and understandable information.

A variety of genetic tests are now increasingly being offered directly to consumers, usually over the Internet. Such genetic testing usually involves scraping a few cells from inside the cheek and mailing the sample to a test laboratory where the test is performed. People considering such genetic tests should discuss the issue with their healthcare provider or a genetic counselor.

Background

Genes and chromosomes

Deoxyribonucleic acid (DNA) is a long molecule made up of two strands of genetic material coiled around each other in a unique double helix structure. This

structure was discovered in 1953 by Francis Crick and James Watson.

DNA is found in the nucleus, or center, of most cells (some cells, such as a red blood cell, do not have a nucleus). Each person's DNA is a unique blueprint, giving instructions for a person's physical traits, such as eye color, hair texture, height, and susceptibility to disease. DNA is organized into structures called chromosomes.

The instructions are contained in DNA's long strands as a code spelled out by pairs of bases, which are four chemicals that make up DNA. The bases occur as pairs, because a base on one strand lines up with and is bound to a corresponding base on the other strand. The order of these bases forms the DNA's code. The order of the bases on a DNA strand is important to ensuring a person is not affected with any genetic disorders. When the bases are out of order or missing, cells may often not produce important proteins; this can lead to a genetic disorder. While genes are found in every cell of the body, not every gene is functioning all of the time. Some genes are turned on during critical points in development and then remain

silent for the rest of an individual's life. Other genes always remain active so that cells can produce important proteins such as those that help digest food properly or fight off the common cold.

The specific order of the base pairs on a strand of DNA is important in order for the correct protein to be produced. A grouping of three base pairs on the DNA strand is called a codon. Each codon, or three base pairs, comes together to spell a word. A string of many codons together can be thought of as a series of words all coming together to make a sentence. This sentence is what instructs cells to make a protein that helps bodies function properly.

DNA strands containing a hundred to several thousand copies of genes are found on structures called chromosomes. Each cell typically has 46 chromosomes arranged into 23 pairs. Each parent contributes one chromosome to each pair. The first 22 pairs are called autosomal chromosomes, or non-sex chromosomes, and are assigned a number from 1 to 22. The last pair are the sex chromosomes and include the X and the Y chromosomes. If a child receives an X chromosome from each parent, the child is female. If a child receives an X from the mother and a Y from the father, the child is male.

Just as each parent contributes one chromosome to each pair, so each parent contributes one gene from each chromosome. The pair of genes produces a specific trait in the child. In autosomal dominant conditions, it takes only one copy of a gene to influence a specific trait. The stronger gene is called dominant; the weaker gene is called recessive. Two copies of a recessive gene are needed to control a trait, while only one copy of a dominant gene is needed. Our sex chromosomes, the X and the Y, also contain important genes. Some genetic diseases are caused by missing or altered genes on one of the sex chromosomes. Males are most often affected by sex chromosome diseases when they inherit an X chromosome with missing or mutated genes from their mother.

Types of genetic mutations

Genetic disease results from a change, or mutation, in a chromosome or in one or several base pairs on a gene. Some of us inherit these mutations from our parents, called hereditary or germline mutations, while other mutations can occur spontaneously, or for the first time in an affected child. For many of the adult-onset diseases, genetic mutations can occur over the lifetime of the individual. These are called acquired or somatic mutations, and occur while the cells are making copies of themselves or dividing in two. There may be some environmental effects, such as

radiation or other chemicals, that can contribute to these types of mutations as well.

There are a variety of different types of mutations that can occur in the genetic code to cause a disease; and for each genetic disease, there may be more than one type of mutation to cause the disease. For some genetic diseases, the same mutation occurs in every individual affected with the disease. For example, the most common form of dwarfism, called achondroplasia, occurs because of a single base pair substitution. This same mutation occurs in all individuals affected with the disease. Other genetic diseases are caused by different types of genetic mutations that may occur anywhere along the length of a gene. For example, cystic fibrosis, the most common genetic disease of the Caucasian population, is caused by hundreds of different mutations along the gene. Individual families may carry the same mutation as each other, but not as the rest of the population affected with the same genetic disease.

Some genetic diseases occur as a result of a larger mutation that can occur when the chromosome itself is either rearranged or altered, or when a baby is born with more than the expected number of chromosomes. There are only a few types of chromosome rearrangements that are possibly hereditary, or passed on from the mother or the father. The majority of chromosome alterations occur sporadically or for the first time with a new baby.

The type of mutation that causes a genetic disease will determine the type of genetic test to be performed. In some situations, more than one type of genetic test will be performed to arrive at a diagnosis. The cost of genetic tests vary: chromosome studies can cost hundreds of dollars and certain gene studies can cost thousands. Insurance coverage also varies with the company and the policy. It may take several days or several weeks to complete a test. Research testing where the exact location of a gene has not yet been identified can take several months or years for results.

Types of genetic testing

Gene tests

Gene tests look for signs of a disease by examining DNA taken from a person's blood, body fluids, or tissues. The tests can look for large changes, such as a gene that has a section missing or added, or small changes, such as a missing, added, or altered chemical base within the DNA strand. Other important changes can be genes with too many copies, genes that are too active, genes that are turned off, or those that are lost entirely.

Various techniques are used for gene tests. Direct DNA sequencing examines the direct base pair sequence

of a gene for specific gene mutations. Some genes contain more than 100,000 bases; a mutation of any one base can make the gene nonfunctional and cause disease. The more mutations possible, the less likely it is for a test to detect all of them. This test is usually done on white blood cells from a person's blood, but can also be performed on other tissues. There are different ways in which to perform direct DNA mutation analysis. When the specific genetic mutation is known, it is possible to perform a complete analysis of the genetic code, also called direct sequencing. There are several different lab techniques used to test for a direct mutation. One common approach begins by using chemicals to separate DNA from the rest of the cell. Next, the two strands of DNA are separated by heating. Special enzymes (called restriction enzymes) are added to the single strands of DNA; they then act like scissors and cut the strands in specific places. The DNA fragments are then sorted by size through a process called electrophoresis. A special piece of DNA called a probe is added to the fragments. The probe is designed to bind to specific mutated portions of the gene. When bound to the probe, the mutated portions appear on x-ray film with a distinct banding pattern.

Another gene test technique is indirect DNA testing. Family linkage studies are done to study a disease when the exact type and location of the genetic alteration is not known, but the general location on the chromosome has been identified. These studies are possible when a chromosome marker has been found associated with a disease. Chromosomes contain certain regions that vary in appearance between individuals. These regions are called polymorphisms and do not cause a genetic disease to occur. If a polymorphism is always present in family members with the same genetic disease, and absent in family members without the disease, it is likely that the gene responsible for the disease is near that polymorphism. The gene mutation can be indirectly detected in family members by looking for the polymorphism.

To look for the polymorphism, DNA is isolated from cells in the same way it is for direct DNA mutation analysis. A probe is added that will detect the large polymorphism on the chromosome. When bound to the probe, this region will appear on x-ray film with a distinct banding pattern. The pattern of banding of a person being tested for the disease is compared to the pattern from a family member affected by the disease.

Linkage studies have disadvantages not found in direct DNA mutation analysis. These studies require multiple family members to participate in the testing. If key family members choose not to participate, the incomplete family history may make testing other members useless. The indirect method of detecting a mutated gene also causes more opportunity for error.

Chromosome tests

Various genetic syndromes are caused by structural chromosome abnormalities. To analyze a person's chromosomes, his or her cells are allowed to grow and multiply in the laboratory until they reach a certain stage of growth. The length of growing time varies with the type of cells. Cells from blood and bone marrow take one to two days; fetal cells from amniotic fluid take 7–10 days.

When the cells are ready, they are placed on a microscope slide using a technique to make them burst open, spreading their chromosomes. The slides are stained: the stain creates a banding pattern unique to each chromosome. Under a microscope, the chromosomes are counted, identified, and analyzed based on their size, shape, and stained appearance.

Types of chromosome tests include the karyotype test and the FISH (fluorescence in situ hybridization) test. In a karyotype test, the chromosomes are counted, and a photograph is taken of the chromosomes from one or more cells as seen through the microscope. Then the chromosomes are cut out and arranged side-by-side with their partner in ascending numerical order, from largest to smallest. The karyotype is done either manually or using a computer attached to the microscope. The FISH test identifies specific regions on chromosomes using fluorescent DNA probes. FISH analysis can find small pieces of chromosomes that are missing or have extra copies and that can be missed by the karyotype test.

Biochemical tests

Genes contain instructions for making proteins and abnormal protein levels can be indicative of a genetic disorder. Biochemical tests look at the level of key proteins. This level can identify genes that are not working normally. These types of tests are typically used for newborn screening. For example, this screening can detect infants who have metabolic conditions such as phenylketonuria (PKU).

Applications of genetic testing

Newborn screening

In the United States, genetic testing is used most often for newborn screening, a major public health program that can find disorders in newborns that have long-term health effects. Newborn screening tests infant blood samples for abnormal or missing gene products. Every year, millions of newborn babies have their blood samples tested for potentially serious genetic diseases. As of 2021, newborn screening programs were testing for disorders that can cause infectious disease, premature death, hearing disorders, metabolic disorders, and heart problems. A

technology called tandem mass spectrometry allows screening of more than 30 other metabolic disorders.

Carrier testing

An individual who has a gene associated with a disease but never exhibits any symptoms of the disease is called a carrier. A carrier is a person who is not affected by the mutated gene he or she possesses, but can pass the gene to an offspring. Genetic tests have been developed that tell prospective parents whether or not they are carriers of certain diseases. If one or both parents are a carrier, the risk of passing the disease to a child can be predicted.

To predict the risk, it is necessary to know whether the gene in question is autosomal or sex-linked. If the gene is carried on any one of chromosomes 1–22, the resulting disease is called an autosomal disease. If the gene is carried on the X or Y chromosome, it is called a sex-linked disease.

Sex-linked diseases, such as the bleeding condition hemophilia, are usually carried on the X chromosome. A woman who carries a disease-associated gene on one of her X chromosomes has a 50% chance of passing that gene to her son. A son who inherits that gene will develop the disease because he does not have another normal copy of the gene on a second X chromosome to compensate for the abnormal copy. A daughter who inherits the disease-associated gene from her mother will be at risk for having a son affected with the disease.

The risk of passing an autosomal disease to a child depends on whether the gene is dominant or recessive. A prospective parent carrying a dominant gene has a 50% chance of passing the gene to a child. A child needs to receive only one copy of the mutated gene to be affected by the disease.

If the gene is recessive, a child needs to receive two copies of the mutated gene, one from each parent, to be affected by the disease. When both parents are carriers, their child has a 25% chance of inheriting two copies of the mutated gene and being affected by the disease; a 50% chance of inheriting one copy of the mutated gene, and being a carrier of the disease but not affected; and a 25% chance of inheriting two normal genes. When only one parent is a carrier, a child has a 50% chance of inheriting one mutated gene and being an unaffected carrier of the disease, and a 50% chance of inheriting two normal genes.

Cystic fibrosis is a disease that affects the lungs and pancreas and is discovered in early childhood. It is the most common autosomal recessive genetic disease found in the Caucasian population: 1 in 25 people of Northern European ancestry are carriers of a mutated cystic fibrosis

gene. The gene, located on chromosome 7, was identified in 1989.

The gene mutation for cystic fibrosis is detected by a direct DNA test. Over 600 mutations of the cystic fibrosis gene have been found; each of these mutations causes the same disease. Tests are available for the most common mutations. Tests that check for 86 of the most common mutations in the Caucasian population will detect 90% of carriers for cystic fibrosis. The percentage of mutations detected varies according to the individual's ethnic background. If a person tests negative, it is likely but not guaranteed that he or she does not have the gene. Both parents must be carriers of the gene to have a child with cystic fibrosis.

Tay-Sachs disease, also autosomal recessive, affects children primarily of Ashkenazi Jewish descent. Children with this disease die between the ages of two and five. This disease was previously detected by looking for a missing enzyme. The mutated gene has now been identified and can be detected using direct DNA mutation analysis.

Presymptomatic testing

Not all genetic diseases show their effect immediately at birth or early in childhood. Although the gene mutation is present at birth, some diseases do not appear until adulthood. If a specific mutated gene responsible for a late-onset disease has been identified, a person from an affected family can be tested before symptoms appear.

Huntington's disease is one example of a late-onset autosomal dominant disease. Its symptoms of mental confusion and abnormal body movements do not appear until middle to late adulthood. The chromosome location of the gene responsible for Huntington's chorea was located in 1983 after studying the DNA from a large Venezuelan family affected by the disease. Ten years later the gene was identified. A test is now available to detect the presence of the expanded base pair sequence responsible for causing the disease. The presence of this expanded sequence means the person will develop the disease.

Another late-onset disease, Alzheimer's, does not have as well an understood genetic cause as Huntington's disease. The specific genetic cause of Alzheimer disease is not as clear. Although many cases appear to be inherited in an autosomal dominant pattern, many cases exist as single incidents in a family. Like Huntington's, symptoms of mental deterioration first appear in adulthood. Genetic research has found an association between this disease and genes on four different chromosomes. The validity of looking for these genes in a person without

symptoms or without family history of the disease is still being studied.

Cancer susceptibility testing

Cancer can result from an inherited (germline) mutated gene or a gene that mutated sometime during a person's lifetime (acquired mutation). Some genes, called tumor suppressor genes, produce proteins that protect the body from cancer. If one of these genes develops a mutation, it is unable to produce the protective protein. If the second copy of the gene is normal, its action may be sufficient to continue production, but if that gene later also develops a mutation, the person is vulnerable to cancer. Other genes, called oncogenes, are involved in the normal growth of cells. A mutation in an oncogene can cause too much growth, which is the beginning of cancer.

Direct DNA tests are currently available to look for gene mutations identified and linked to several kinds of cancer. People with a family history of these cancers are those most likely to be tested. If one of these mutated genes is found, the person is more susceptible to developing the cancer. The likelihood that the person will develop the cancer, even with the mutated gene, is not always known because other genetic and environmental factors are also involved in the development of cancer.

Cancer susceptibility tests are most useful when a positive test result can be followed with clear treatment options. In families with familial polyposis of the colon, testing a child for a mutated *APC* gene can reveal whether or not the child needs frequent monitoring for the disease. In families with potentially fatal familial medullary thyroid cancer or multiple endocrine neoplasia type 2, finding a mutated *RET* gene in a child provides the opportunity for that child to have preventive removal of the thyroid gland. In the same way, *MSH1* and *MSH2* mutations can reveal which members in an affected family are vulnerable to familial colorectal cancer and would benefit from aggressive monitoring.

In 1994, a mutation linked to early-onset familial breast and ovarian cancer was identified. *BRCA1* is located on chromosome 17. Women with a mutated form of this gene have an increased risk of developing breast and ovarian cancer. A second related gene, *BRCA2*, was later discovered. Located on chromosome 13, it also carries increased risk of breast and ovarian cancer. Although both genes are rare in the general population, they are slightly more common in women of Ashkenazi Jewish descent.

When a woman is found to have a mutation in one of these genes, the likelihood that she will get breast or ovarian cancer increases, but not to 100%. Other genetic and environmental factors influence the outcome.

Testing for these genes is most valuable in families where a mutation has already been found. *BRCA1* and *BRCA2* are large genes; *BRCA1* includes 100,000 bases. More than 1,600 mutations to this gene have been discovered, but a mutation could occur in any one of the bases. Studies show tests for these genes may miss 30% of existing mutations. The rate of missed mutations, the unknown disease likelihood in spite of a positive result, and the lack of a clear preventive response to a positive result make the value of this test for the general population uncertain.

Prenatal and postnatal chromosome analysis

Chromosome analysis is performed on fetal cells primarily when the mother is age 35 or older at the time of delivery, has experienced multiple miscarriages, or reports a family history of a genetic abnormality. Prenatal testing is done on the fetal cells from a chorionic villus sampling (from the baby's developing placenta) at 10–12 weeks or from the amniotic fluid (the fluid surrounding the baby) at 16–18 weeks of pregnancy. Cells from amniotic fluid grow for 7–10 days before they are ready to be analyzed. Chorionic villi cells have the potential to grow faster and can be analyzed sooner.

Chromosome analysis using blood cells is done on a child who is born with or later develops signs of mental retardation or physical malformation. In the older child, chromosome analysis may be done to investigate developmental delays.

Extra or missing chromosomes cause mental and physical abnormalities. A child born with an extra chromosome 21 (trisomy 21) has Down syndrome. An extra chromosome 13 or 18 also produces well-known syndromes. A missing X chromosome in a female causes Turner syndrome, and an extra X in a male causes Klinefelter syndrome. Other abnormalities are caused by extra or missing pieces of chromosomes. Fragile X syndrome is a sex-linked disease that causes mental retardation in males.

Chromosome material may be rearranged, such as the end of chromosome 1 moving to the end of chromosome 3. This is called a chromosomal translocation. If no material is added or deleted in the exchange, the person may not be affected. Such an exchange, however, can cause infertility or abnormalities if passed to children.

Evaluation of a man and woman's infertility or repeated miscarriages includes blood studies of both to check for a chromosome translocation. Many chromosome abnormalities are incompatible with life; babies with these abnormalities often miscarry during the first trimester. Cells from a baby that died before birth can be

studied to look for chromosome abnormalities that may have caused the death.

Diagnostic testing

This type of genetic testing is used to confirm a diagnosis when a person has signs or symptoms of a genetic disease. The genetic test used depends on the disease for which a person is tested. For example, if a patient has physical features indicative of Down syndrome, a chromosomal test is used. To test for Duchenne muscular dystrophy, a gene test is done to look for missing sections in the dystrophin gene.

Chromosome tests are used to diagnose certain cancers, particularly leukemia and lymphoma, which are associated with changes in chromosomes: extra or missing complete chromosomes, extra or missing portions of chromosomes, or exchanges of material (translocations) between chromosomes. Studies show that the locations of the chromosome breaks are at locations of tumor suppressor genes or oncogenes.

Chromosome analysis on cells from blood, bone marrow, or solid tumors helps diagnose certain kinds of leukemia and lymphoma and often helps predict how well the person will respond to treatment. After treatment has begun, periodic monitoring of these chromosome changes in the blood and bone marrow gives the physician information as to the effectiveness of the treatment.

A well-known chromosome rearrangement is found in chronic myelogenous leukemia. This leukemia is associated with an exchange of material between chromosomes 9 and 22. The resulting smaller chromosome 22 is called the Philadelphia chromosome.

Pharmacogenetic testing

The latest type of genetic testing is pharmacogenetic testing. This test examines a person's genes to gain

information on how drugs would be broken down by the body. Pharmacogenetic testing aims to design drug treatments that are specific to each person. For example, a test used in patients who have chronic myelogenous leukemia can show which patients would benefit from a medicine called Gleevec. Another test looks at a liver enzyme called cytochrome P450, which breaks down certain types of drugs. Gene mutations can affect the ability of the body to break down certain drugs, and people with a less active form of P450 might be taking excessive levels of a drug. Pharmacogenetic testing seeks to help patients obtain the right dosage of a medication.

Preparation

Most tests for genetic diseases of children and adults are done on blood. To collect the 5–10 mL of blood needed, a healthcare worker draws blood from a vein in the inner elbow region. Collection of the sample takes only a few minutes.

Prenatal testing is done either on amniotic fluid or a chorionic villus sampling. To collect amniotic fluid, a physician performs a procedure called amniocentesis. An ultrasound is done to find the baby's position and an area filled with amniotic fluid. The physician inserts a needle through the woman's skin and the wall of her uterus and withdraws 5–10 mL of amniotic fluid. Placental tissue for a chorionic villus sampling is taken through the cervix. Each procedure takes approximately 30 minutes.

Bone marrow is used for chromosome analysis in a person with leukemia or lymphoma. The person is given local anesthesia. Then the physician inserts a needle through the skin and into the bone (usually the sternum or hip bone). One-half to 2 mL of bone marrow is withdrawn. This procedure takes approximately 30 minutes.

Aftercare

After blood collection, the person can feel discomfort or bruising at the puncture site, or may become dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

The chorionic villus sampling, amniocentesis, and bone marrow procedures are all done under a physician's supervision. The person is asked to rest after the procedure and is watched for weakness and signs of bleeding.

Risks

Collection of amniotic fluid and chorionic villus sampling have the risk of miscarriage, infection, and bleeding; the risks are higher for the chorionic villus

sampling. Because of the potential risks for miscarriage—0.5% following the amniocentesis and 1% following the chorionic villus sampling procedure—both of these prenatal tests are offered to couples, but not required. A woman should tell her physician immediately if she has cramping, bleeding, fluid loss, an increased temperature, or a change in the baby's movement following either of these procedures.

After bone marrow collection, the puncture site may become tender and the person's temperature may rise. These are signs of a possible infection.

Genetic testing involves other nonphysical risks. Many people fear the possible loss of privacy about personal health information. Results of genetic tests may be reported to insurance companies and affect a person's insurability. Some people pay out-of-pocket for genetic tests to avoid this possibility. Laws have been proposed to deal with this problem. Other family members may be affected by the results of a person's genetic test. Privacy of the person tested and the family members affected is a consideration when deciding to have a test and to share the results.

A positive result carries a psychological burden, especially if the test indicates the person will develop a disease, such as Huntington's chorea. The news that a person may be susceptible to a specific kind of cancer, while it may encourage positive preventive measures, may also negatively shadow many decisions and activities.

A genetic test result may also be inconclusive, meaning no definitive result can be given to the individual or family. This may cause the individual to feel more anxious and frustrated and experience psychological difficulties.

Prior to undergoing genetic testing, individuals need to learn from the genetic counselor the likelihood that the test could miss a mutation or abnormality.

Normal results

A normal result for chromosome analysis is 46, XX or 46, XY. This means there are 46 chromosomes (including two X chromosomes for a female or one X and one Y for a male) with no structural abnormalities. A normal result for a direct DNA mutation analysis or linkage study is no gene mutation found.

There can be some benefits from genetic testing when the individual tested is not found to carry a genetic mutation. Those who learn with great certainty they are no longer at risk for a genetic disease may choose not to undergo prophylactic therapies and may feel relieved and less anxious.

Abnormal results

An abnormal chromosome analysis report includes the total number of chromosomes and identifies the abnormality found. Tests for gene mutations report the mutations found.

There are many ethical issues to consider with an abnormal prenatal test result. Many of the diseases tested for during a pregnancy cannot be treated or cured. In addition, some diseases tested for during pregnancy may have a late onset of symptoms or have minimal effects on the affected individual.

Before making decisions based on an abnormal test result, the person should meet again with a genetic counselor to fully understand the meaning of the results, learn what options are available based on the test result, and learn the risks and benefits of each of those options.

Genetics and congenital anomalies

Definition

Any unusual variation or abnormality in the shape, structure, and/or function of an organ, body part, or tissue is commonly referred to as a birth defect. However, *congenital anomaly* is the more accurate and preferred term, since birth defect can be misinterpreted to mean a defect produced by the birthing process. Congenital anomalies may be external or internal, single (isolated) or multiple, major or minor, and by definition are present at (and almost always before) birth, although in some cases detection/diagnosis occurs well after birth. As a group, congenital anomalies are common, have a wide range of clinical severity, and can develop in one form or another in any anatomical structure or location. There are many different causes of congenital anomalies, known and unknown, but in terms of how they develop, there are four major types: malformations, deformations, disruptions, and dysplasias.

Description

Variation among individuals in physical characteristics, both external and internal, is an essential attribute of any organism that reproduces sexually, including humans. Although less obviously, but no less importantly, people also differ in their metabolism and other cellular/chemical processes that help form and maintain the body. The process of normal development in the body is called morphogenesis, while abnormal development is known as dysmorphogenesis. Dysmorphology, then, is the study of congenital anomalies, including their formation, causes, and patterns of occurrence.

An important task in both medical and sociocultural contexts lies in determining what constitutes a congenital anomaly, and what qualifies as an accepted morphological variant. Further, what distinguishes a major anomaly from a minor one? In other words, what is normal, and what is abnormal? In some cases, the distinction is obvious; in others it is not. Terms such as *normal* and *abnormal* are generally agreed to be subjective, and thus not applicable when applied to individuals in a broad context. The same can be said of terms such as defective, anomalous, deformed, malformed, aberrant, irregular, and the like. Even though some terms and phrases are perceived as subjective, negative, and offensive when misapplied as generalities, they are nonetheless necessary in a medical context. With due sensitivity and care, these same terms can be used clinically in an objective and instructive manner.

Compared with the complex and evolving social issues of perception and acceptance, the medical approach to distinguishing normal variants from minor and major anomalies is more objective and direct. Regardless of the anatomical structure or process, the primary criterion involves evaluating whether its function, shape, structure, and/or size fall within or outside the normal (expected) range. To help answer that question, measurements of every conceivable type have been taken and catalogued over the years on countless individuals. Statistical formulas are applied to the data for a given characteristic or function (e.g., height, weight, blood pressure, serum enzyme levels, etc.) to determine its normal range. If needed, adjustments for age, sex, race, ethnicity, and many other variables can also be made. The results are often graphed and, for most human characteristics, a line drawn through the data points on the graph produces the well-known bell curve, a name derived from its shape. Calculations based on such factors as the total number of individuals studied and the range of measurements obtained, among others, are used to mark off a section in the middle of the curve such that most individuals (usually between 80% and 95%) fall within that range. Therefore, any values above or below (i.e., outside) that range are considered anomalous or abnormal. Measured values for minor anomalies might fall several percentage points on either side of the upper and lower boundaries of the normal range, while major anomalies lie at the ends of the curve.

Among other new challenges, parents and families of children with congenital anomalies are exposed to a bewildering array of new medical terms and phrases, and asked to understand, process, and remember these while likely under a great deal of stress. The practice of medical genetics consists primarily of communicating with individuals and families about difficult and complex issues. Geneticists and genetic counselors are especially sensitive to the psychosocial impact terminology can have on perception and understanding of congenital anomalies/genetic disorders. Parents of a newly diagnosed child inevitably want to know how the anomaly or genetic syndrome occurred. An understanding of the different types of anomalies is the basis for answering that question.

Malformations

A malformation is an abnormality in the shape or structure of an organ, body part, or larger section of the body resulting from an intrinsically dysfunctional developmental process. In other words, the genetic instructions for development are faulty, interfered with, or both.

All cells in the body carry the same set of genes, copied from the original set provided by the sperm and the

KEY TERMS

Association—A non-random occurrence in two or more individuals of the same group of anomalies that are not otherwise known to be a sequence or syndrome.

Congenital—Present at birth.

Deformation—Abnormal shape or function in otherwise normal tissue produced by unusual mechanical forces on the embryo/fetus.

Disruption—A type of anomaly formation in which a breakdown or inhibition of normal tissue development occurs.

Dysmorphic—Literally meaning misshapen, it is most often used as a general descriptive term for individuals with one or more anomalous physical characteristics.

Dysplasia—The structural and functional results of the abnormal organization of cells into tissues, affecting one or more of the derivatives of a primary tissue type (endoderm, mesoderm, or ectoderm).

Etiology—The cause of a disease, syndrome, or anomaly.

Idiopathic—One or more anomalies of unknown cause in an individual.

Malformation—An abnormality in an organ or body structure caused by a dysfunctional developmental process.

Morphogenesis—The normal developmental process of the body's structure and form.

Sequence—The combination of both a primary structural or functional anomaly, and the secondary anomalies produced by any abnormal forces or processes it generates.

Syndrome—A pattern of multiple major and minor anomalies that occur as a group more often than would be expected by chance alone, implying the same underlying cause or mechanism in all affected individuals.

egg at conception. Some genes are primarily responsible for directing a portion of embryonic/fetal development, and their influence may be anywhere from general (entire body or entire tissue) to specific (small component of one organ). This is why many single-gene (inherited) and most chromosomal disorders are characterized by multiple major and minor malformations in various anatomic locations. Any disorder, including most with a genetic basis, that can be uniquely characterized by a specific

group of anomalies that occur more frequently together in that condition than would be expected by chance is defined as a syndrome. Multiple malformation patterns that have no discernible or consistent genetic pattern or teratogenic cause are known as associations (e.g., the VACTERL or VATER association).

Most isolated malformations follow a multifactorial inheritance pattern, and often involve incomplete morphogenesis of a midline organ or structure (e.g., septal defects [holes] in the heart, cleft lip/palate, diaphragmatic hernia, or spina bifida). These same types of malformations occur in some syndromes, in combination with a wide variety of other malformation types. Organs, body parts, or other structures may be extra/missing, abnormally positioned, overdeveloped (hyperplastic), underdeveloped (hypoplastic), or any of a number of minor variations.

Deformations

A deformation is an anomaly in the form, shape, or position of a body part or section that results from mechanical forces on the embryo/fetus. Deformations can have extrinsic (outside the fetus) or intrinsic (internal) causes. Examples of possible extrinsic causes include small maternal stature, oligohydramnios (decreased amniotic fluid volume), breech presentation, uterine malformation, and multiple pregnancy (i.e., twins, triplets, etc.). Some intrinsic (fetal) factors capable of producing deformations include neuromuscular disease, connective tissue defects, central nervous system disorders, and kidney malformations.

Joint contractures, such as talipes equinovarus (club-foot), are the most common type of deformation, and have both extrinsic and intrinsic causes. As the fetus develops and grows, it must be able to move (flex and extend) the joints or they can become locked in position (contracted). Chronic oligohydramnios produces intrauterine constraint (IUC), which compresses and immobilizes the fetus, causing joint contractures. Oligohydramnios itself may be caused by leakage of fluid from the amniotic sac (extrinsic cause), or result from decreased fluid production secondary to malformation or absence (agenesis) of the fetal kidneys. (Amniotic fluid is comprised mostly of fetal urine in the later stages of pregnancy.)

Agenesis of the fetal kidneys also exemplifies a malformation/deformation sequence. Specifically, an original isolated malformation (renal agenesis) produces a sequence of events (oligohydramnios plus IUC plus fetal compression) that results in deformations, such as joint contractures and a characteristic facial pattern, which is sometimes referred to as the Potter sequence. A neuromuscular disease that causes partial or total prenatal

paralysis of the limbs (decreased mobility) is another example of an intrinsic cause of joint contractures.

Disruptions

A disruption is an anomaly of an organ or body structure resulting from an extrinsic factor that interferes with, or disrupts, an originally normal developmental process. For example, certain types of maternal infection or drug use at a critical time in pregnancy have the potential to arrest the developmental process in specific fetal tissues. Another type of disruption can occur when a strip of the amniotic membrane surrounding the fetus detaches and wraps around one of the developing limbs or a section of the body. Known as an amniotic band, it acts somewhat like a tourniquet, restricting blood flow and inhibiting further growth.

Dysplasias

Dysplasia refers to an abnormal organization of cells in a particular tissue type, and any resulting abnormal morphological development. Dysplasias usually have a genetic basis, and examples include skeletal dysplasias (e.g., fragile, short, and/or abnormally curved bones), ectodermal dysplasias (skin, hair, nails, and associated tissues), and renal dysplasias (multiple cysts or tumors in the kidneys).

Genetic profile

Of all major congenital malformations, 60% have an undetermined cause, and 20% are attributed to multifactorial inheritance. The remaining 20% are divided roughly equally between single-gene disorders, chromosomal syndromes, and teratogenic causes. Considering that inclusion in the multifactorial group does not imply a specifically determined cause in any particular case, about 80% of all major malformations have no readily identifiable cause. The most frequently malformed organs are the brain, heart, and urinary tract (kidneys, ureters, bladder, and urethra). Deformations and disruptions most often affect the extremities (hands and feet), limbs (arms and legs), skull, and face.

Multifactorial inheritance is assumed for most isolated congenital anomalies, with a risk for recurrence in subsequent pregnancies of 3%–5%. Single-gene (e.g., autosomal dominant, autosomal recessive, sex-linked, etc.) and chromosomal syndromes present a broad range of recurrence risks, but most often are 1%–3% for chromosomal syndromes, and 25% or 50% for single-gene disorders.

Demographics

Considered individually, most anomalies and genetic syndromes are uncommon, and some are quite rare. As a category, however, they are quite common. Major congenital anomalies are the leading cause of death for children less than one year old, and the second and third most frequent cause for those less than five and fifteen years old, respectively. Approximately 40% of all pediatric hospital admissions are related to congenital anomalies.

Malformations may be isolated or multiple, with minor or major clinical significance. Of all newborns, about 14% have a single minor malformation, 3% have a single major malformation, and up to 0.7% have multiple major malformations. The frequency of major malformations is even higher at conception, estimated at 10%–15%, but most of these result in spontaneous pregnancy loss. About 2% of newborns are found to have a disruption of some type. In the presence of a major congenital malformation, especially if it affects the central nervous system or urinary tract, there is an 8% risk that a deformation will also occur. Skeletal dysplasias have an overall incidence of about 0.5%, with diagnosis of some of the milder forms often delayed until childhood. Ectodermal dysplasias occur in about 0.7% of individuals, but only several types associated with major malformations are usually diagnosed at birth. Other forms of congenital dysplasias are rare.

Diagnosis

Many anomalies are now detected/diagnosed prenatally, either through testing chosen because of a known or suspected risk factor; as a coincidental finding during testing chosen for another purpose; or as a chance finding during routine prenatal evaluations. Prenatal testing is done either through imaging studies, most often routine (level I) or detailed (level II) obstetric ultrasound, or through direct biochemical or genetic testing of the fetus using chorionic villus sampling (CVS) or amniocentesis. Fetal echocardiography is sometimes used to confirm heart defects, and some rare conditions might require x-rays or magnetic resonance imaging (MRI) of the fetus (via the mother), while a few others can only be diagnosed by a fetal skin biopsy. Some tests are designed only to screen for certain anomalies or syndromes (increase or decrease the likelihood).

Evaluating congenital anomalies postnatally usually involves attempts to confirm the suspected or most likely diagnosis, while at the same time excluding other possible diagnoses. Major external anomalies are easily detected, but those affecting internal organs require recognition of the signs and symptoms they produce (e.g., a baby with breathing difficulty who turns blue [cyanotic]

while crying may have a heart defect), which could be subtle and/or not appear until well after birth.

Any child with an apparently isolated congenital anomaly should have it confirmed (i.e., exclude subtle or hidden signs of an association or syndrome). Multiple congenital anomalies are best evaluated by a geneticist, if possible, even in cases involving an obvious diagnosis, such as a common condition like Down syndrome. The family may wish to have a consultation in a genetics clinic, where a comprehensive approach helps to ensure that a thorough evaluation and explanation of the condition are provided. In addition, psychosocial issues are addressed, appropriate referrals can be made (e.g., other specialists, support groups, or more extensive psychological assistance as needed), and the most complete and current information on testing and other options are available. In cases with an unusual presentation of symptoms, or rare syndromes, geneticists have the best chance of establishing a diagnosis, often in consultation with colleagues who specialize in a particular syndrome or class of disorders. In other situations, a geneticist might suggest periodic reevaluations if a diagnosis is unclear initially, since some children grow into a syndrome (i.e., the defining characteristics only become apparent as the child grows). Unfortunately, all too often a diagnosis is never established, regardless of effort expended or specialists consulted. Even in these cases, a geneticist may be able to offer a reasonable estimation as to a cause and recurrence risk, based on a process of eliminating some factors, making others more likely, and applying any available empirical data from similar cases.

Regardless of situation, a genetics evaluation includes as many of the following as possible:

- a complete physical examination of the affected child
- a review of medical records
- evaluation of the pregnancy history
- a consultation to obtain and evaluate the medical history of the immediate and extended family

Based on these evaluations, one or more of a wide variety of possible medical tests could be suggested. If a hereditary syndrome is suspected, physical examination, medical record review, and testing might also be requested of one or more family members to help establish a diagnosis. The importance of making a diagnosis rests in the ability it provides to answer other questions parents inevitably have. The diagnostic process also attempts to determine how a malformation, deformation, disruption, dysplasia, or some combination occurred.

Treatment and management

Deformations are typically more amenable to successful treatment and correction than other types of anomalies. For instance, infants with dislocated hips or clubfeet can usually achieve normal function after a regimen of bracing, casting, and movement therapy, although in some cases minor surgery is necessary. Many malformations can also be successfully repaired, especially those that are isolated. However, invasive and complex surgery is often needed, with only partial improvement in some cases. Certain malformations, such as cleft lip/palate, require multiple surgeries performed in stages as the child grows. For the most part, disruptions and dysplasias are minimally treatable, if at all. However, an exception could be the use of a prosthetic device for a limb amputation anomaly caused by a disruption such as an amniotic band.

Prognosis

The prognosis for any particular congenital anomaly, whether isolated or part of a sequence or syndrome, can vary greatly. Medical complications from one anomaly may adversely affect the prognosis of another, or affect the course of an entire syndrome. In general, however, children with extrinsically caused deformations tend to fare better than those with other types of anomalies. Likewise, isolated malformations usually carry a better prognosis than multiple malformations/deformations, intrinsically derived deformations, and most types of tissue dysplasia. Disruption anomalies have widely varying prognoses based on various factors, such as the organ or body parts affected, the degree of disruption, and the timing during morphogenesis at which the disruption began.

Genome

Definition

A genome is the complete set of genetic material needed to create and maintain a living organism. In humans, a genome consists of 24 chromosome pairs and between 20,000 and 25,000 individual genes.

Description

Within each cell there is a substance called deoxyribonucleic acid or DNA. Groups of DNA pairs join to form genes, and genes join to form chromosomes. A genome is the complete grouping of this material. It contains all the instructions necessary for life. Every function of the body, all that makes a human a unique individual, and all information needed to reproduce is controlled by genes within the genome.

Genes are composed of specific sequences of building blocks called nucleotides. There are only four specific nucleotides that make up all genetic material. They are commonly abbreviated as A, C, G, and T for adenine, cytosine, guanine, and thymine. These four nucleotides only appear in specific pairings. A and T will only pair with each other or with another A or T nucleotide, and C and G will only pair with each other or with another C or G. The entire human genome is based on pairings of these four nucleotides. There are more than three billion of these pairs in a human genome.

Genes comprise only approximately 2% of the entire human genome. The remaining parts of the genome consist of areas called noncoding regions that regulate production of proteins necessary to strengthen genes, regulate the expression of genes, and conduct other biochemical functions.

Gene sequencing

More commonly known as gene sequencing, genetic profiling is the process by which the genetic

characteristics of individuals are identified. Through a process called personal DNA analysis, DNA profiling, or DNA sequencing, researchers are able to create a map of an organism's DNA by identifying the individual base nucleotides. Because each person's genetic profile is unique, it is sometimes called a genetic fingerprint.

Genetic sequencing was first completed using ribonucleic acid (RNA) material and then DNA. RNA is genetic material essential in the production of proteins and in the transmission of genetic information. Genetic sequencing may be performed using samples of hair, skin, saliva, or blood, and an instrument known as a sequencer.

Beginning in the 1970s, researchers sought to identify and map the human genome. At that time, it took several months to sequence a single base pair. In 1990, researchers began the Human Genome Project with the goal of identifying the entire human genome. This goal was accomplished in 2003 with the sequencing of the complete human genome. The mapping of the human genome has inspired ongoing investigation and discoveries of the significance of genes and human health.

Gene sequencing may be broken into two main types: whole exome sequencing (WES) and whole genome sequencing (WGS). WES focuses on only the portion of the human genome known as coding DNA. Coding DNA contains material that actively produces

KEY TERMS

DNA—Deoxyribonucleic acid, the main component in chromosomes and the substance that carries all genetic material.

Gene sequencing—The process of mapping the order of DNA or genetic material in an organism.

Nucleotides—The building blocks of genes, which are arranged in specific order and quantity.

Pharmacogenetics—The study of how medication metabolism is affected by genetic inheritance.

proteins needed to create genetic material that expresses traits. WGS maps the entire genome, both coding and non-coding sections of the genome. Non-coding DNA is estimated to be more than 80% of the total material in the human genome. When this material was first discovered, it was believed that it served no purpose and was sometimes referred to as “junk DNA.” As the human genome has been sequenced and studied, functional activities for non-coded DNA have been discovered. In some cases, it is believed that this non-coded DNA may interact with environmental factors to produce medical conditions such as bipolar disorder and some types of cancer.

For many years the Sanger method was the gold standard for gene sequencing. Developed in 1977 by geneticist Frederick Sanger, this method uses single strands of DNA that have been separated from the matching pair by a chemical process. This single chain is then subjected to another process that limits the chain to a shortened, specific length. The shortened sections are then ordered by length. Then the base nucleotides are identified. Based on this identification, the entire gene sequence may be known. While the Sanger method is still used in many laboratories, newer methods called next-generation sequencing (NGS) are used in larger commercial laboratories to produce maps of various genes and genetic material.

NGS uses small fragments of DNA to identify individual nucleotide sequences by using a generic DNA strand template and recreating the sequence from the sample DNA provided. The advantage to NGS is that by using modern sequencing equipment, it may be performed across millions of DNA strands at once rather

than the limited number of strands that may be sequenced via the Sanger method.

Multiple programs have researched and are currently researching the potential of whole-genome sequencing (WGS) in predicting disease. In January 2015, the results of a study exploring the efficacy of WGS in diagnosing the risk of developing cancer were published. The researchers in this study examined the whole genome of individuals with cancer who have mutations in the *BRCA* gene. Mutations in the *BRCA* gene may cause an increased risk of developing breast and ovarian cancer. They compared the WGS results of these patients with cancer patients who did not have *BRCA* mutations and discovered that while many of the mutations they discovered were mutations of unknown significance, they were able to predict cancer risk in 21% of patients who did not have the *BRCA* mutations.

The Human Genome Project

In 1990, the National Institutes of Health (NIH), the U.S. Department of Energy, and other international organizations began a program called the Human Genome Project. The NIH called it one of the greatest feats of exploration in history. The goal was to sequence the complete set of DNA in the human body. Completed in April 2003, the Human Genome Project led to the ability for the first time to read the complete genetic blueprint of a human being.

The completion of the Human Genome Project and advancing technology that has made genetic testing more affordable have led to an increase in medical centers and genetics labs that routinely perform gene sequencing. As a result, more than 80 million unique differences in genes and in uncoded regions have been discovered. The challenge doctors and researchers face is determining which of these differences or variants is important.

Implications

Discoveries found within the human genome determine all biological characteristics of an individual. This genetic material also determines signs and symptoms of genetically caused diseases and medical conditions. Therefore, gene sequencing of the human genome is used to diagnose many medical conditions, specifically conditions with known genetic causes. Researchers have discovered several genetic markers that may be useful in predicting which lung cancer patients may develop metastatic cancer in the future, while other studies have found that genomic markers are not as effective at determining survival rates for cancer patients as are other molecular features that control transcription and other biological

functions involved with genetics rather than functions of DNA expression.

Genetic mapping may also be useful when treating patients. According to the National Institutes of Health (NIH), more than two million Americans have serious side effects from prescription medicines each year, and as many as 100,000 die from these effects. Using genomics, doctors may be able to tailor medications to an individual's specific genome and improve medication safety and efficacy. The science of pharmacogenetics seeks to improve health outcomes by combining the science of genomics and pharmacology.

Genetic sequencing is used to help identify a person's risk for developing certain diseases, diagnose medical conditions, and determine the best course of treatment. In the future, individualized, custom medical treatment may be developed based on an individual's specific genome.

The future of human genetics lies in the quest to determine the significance of the information discovered in the Human Genome Project and in the ongoing discoveries of the human genome.

Genome- and epigenome-wide association studies

Definition

The completion of the Human Genome Project and the development of time- and cost-effective methods of sequencing the genome of an individual have changed how we understand genetics and genetic variants. In this post-genome-association era, many more studies can be done to further understand the role of genes in organisms in both coding and non-coding regions of the genome we inherited, and the epigenome it turns into as we change over time and are impacted by our environment. Genome-wide association studies (GWASs) and epigenome-wide association studies (EWAS) are utilized to help understand the human genome and its relationship to mutations, as well as how the sum of interactions between genes, and between genes and the environment, makes us who we are. This information can then be applied to understanding the pathogenesis and heritability of genetic disorders.

Description

The Human Genome Project has had a major impact on the world of genetics. The result of the project—the mapping of every gene and the sequence of the billions of nucleotides that make up these genes in the entire human genome—has led to new understanding of the role of genes and their interactions in regard to the structure and function of the human body, both normal and abnormal. Other projects and technologies such as Sanger sequencing, genome sequencing, and next-generation sequencing have been instrumental in the timely sequencing of individual genomes from DNA (deoxyribonucleic acid). Comparing and associating the genome of an abnormal gene sequence to the known normal human genome sequence, known as the HapMap, has allowed doctors and scientists to diagnose and treat patients more efficiently. Many genetics-related diseases can now be associated with mutations in specific genes, creating an entire database of genetic diseases.

GWAS and EWAS are studies that utilize the human genome sequence to scan for markers in the genome associated with certain disorders. Understanding of the role of

KEY TERMS

Allele—One of two or more different genes encoding specific and inheritable characteristics that occupy corresponding locations on a pair of chromosomes.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

DNA methylation—The addition of methyl groups (CH_3) to nucleotide bases of DNA to regulate gene expression.

Genome—The entire DNA sequence of a cell or organism.

Human Genome Project—An international effort begun in 1990 and completed in 2003 to locate and identify the 100,000 genes on the 46 human chromosomes.

Locus—The position occupied by a gene on a chromosome.

Nucleotides—The building blocks of genes, which are arranged in specific order and quantity.

Single-nucleotide polymorphism—Single nucleotide variant (SNV); a variation or point mutation in a single nucleotide building block of DNA.

these genes has proven to be integral to understanding genetic diseases. GWAS and EWAS are carried out by comparing the genomes of persons with the disease and similar persons without the disease. If the result of the study shows an increase in particular variations in the genomes of those with the disease, using biomarkers on SNPs, then the variations are said to be associated. With this information, researchers can target the roles of these genes to up-regulate or down-regulate as needed to alter the treatment and management of the disease. One example is the use of tyrosine kinase inhibitors in certain cancers such as breast and prostate cancer, since an alteration in the genes related to tyrosine kinase is linked to these cancers. Complex diseases can now be further researched in this post genome- and epigenome-association era.

In the post-genome-association era, there are many more studies that can be done to determine the relationship between multiple genes and gene variants that

contribute to or are the primary causes of complex diseases. These gene variants, typically single-nucleotide polymorphisms (SNPs), are the current challenge in understanding the mechanisms behind complex diseases, either inherited or non-inherited. SNPs are single nucleotide variations in one of the billions of nucleotides that make up the chain of DNA and, therefore, genes in the human genome. SNPs can cause a wide range of changes in the genome, from no changes at all to severe changes such as in the development of a chromosome that leads to the termination of a developing fetus, depending on the location and amount of SNPs that occur.

A new era

Studies being done in the post-genome-association era are focused toward understanding the role and effect of SNPs and also non-coding regions in the human genome, particularly SNPs in the non-coding regions. SNPs can be very complex, as some have a role in the regulation of other genes. Studies are also being performed on complex osteoarthritis diseases such as rheumatoid arthritis (RA); systemic lupus erythematosus, also referred to as lupus (SLE); ankylosing spondylitis (AS); osteoporosis; and osteosarcomas, among others. Genome-wide association studies have determined multiple gene loci related to these bone and autoimmune disorders. Although this information is available, there are still many questions related to their inheritability and the relationship between the loci alterations that account for the sum total of the changes in each disorder.

Using what is already known about osteoarthritic disorders, studies are being done to determine the molecular pathways and mechanism of pathology, to further understand and then treat and possibly even prevent these disorders from occurring in an individual. One such study has determined an altered methylation in the genome of people with osteoarthritic disorders. Methylation is extremely important in the structure and function of genes, and the regulation of the expression of genes. These findings can be used by pharmaceutical researchers for the development of more effective drugs to treat the symptoms or suppress the expression of methylation-related disorders.

Studies are also being performed using the information available about SNPs to fully understand the inheritance of disorders and apply that information to other complex diseases such as cancer. One such study has worked to quantify local inheritability, and has shown groups of diseases such as autoimmune diseases to have alterations in similar loci. Information such as this can be utilized in further studies regarding the loci and inheritability of common diseases such as cancer that are not well understood in terms of genetics and inheritance.

Although much information is available, there are still many questions related to the inheritability of genetic disorders and the relationship between the loci of alterations that account for the changes in each disorder. GWAS may, in the future, help researchers to understand genetic variance between people and the relationship between gene expression and the environment.

Genome sequencing

Definition

Genome sequencing is a method of determining the order of the genetic code of the human body, comparing normal and potentially abnormal sequences. The human genome project has mapped the entire human genome, helping researchers better understand how the genetic code works and why. By understanding the genetic code, scientists can learn how genes work together for the overall structure and function of the human body. Scientists can then compare the genome of individuals for diagnostic purposes and learn more about genetic variations and disorders.

Description

The human genome is the foundational code that makes up not only our structure and function, but also what we are as a genus and species. Each species has its own unique genome. This explains the many differences between species with the same genus, as well as the reason why reproduction can only occur within the same species.

The genome is comprised of the complete set of DNA (deoxyribonucleic acid) and all of its associated genes. The Human Genome Project, an international genome research project conducted from 1990 to 2003, determined the roughly three billion sequences of four nucleic acids that the human genome is made up of. With this information, the research alliance was also able to determine the 25,000 (approximately) genes that are coded based on the DNA sequence and the location of these genes on each of the autosomal and sex chromosomes in the human body.

Ninety-nine percent of humans share the exact same genome. Variations from the norm in the genetic code result in abnormalities and genetic disorders. These variations occur when the code is being replicated to produce new individuals as seen in meiosis, or when the code is being replicated for cell growth and proliferation as seen in mitosis. Comparing abnormal code to normal code will help scientists understand the relationship between the genome and genetic abnormalities such as disorders and pathologies.

Genome sequencing has led to the correlation of genetic disorders and their underlying gene abnormality. Many more phenotypes can be diagnosed and associated to a genotype now that this information is confirmed. This information can also be applied to the development of pharmaceuticals and other treatment and management protocols that are essential in improving the prognosis of an individual with a genetic variation. Knowing and understanding the exact location and mechanism by which a genetic variation is formed, and therefore inherited, has also allowed for in vitro genetic screenings and diagnosing to be effectively performed. Additionally, the human genome and genome sequencing will ideally help researchers fully understand not only genetic anomalies, but also the development of pathologies such as cancers, and how to best treat those cancers.

Genome sequencing in non-humans has also allowed researchers to better understand the biological functions of organisms such as viruses, bacteria, protozoa, and prions among others. Much like the way researchers use the information gained from the human genome sequence, researchers can utilize the information obtained from these organisms and apply it to treatment and

A laboratory assistant analyzes a DNA sequence on the computer. (*science photo/Shutterstock*)

management protocols to fight against the diseases they cause within humans.

Methods

Genome sequencing of an individual is very useful in determining the genetic cause of a disorder for all Mendelian genetic disorders. This information can lead to a development of treatment and management options, genetic testing of future offspring, and possibly prevention of a disorder. There are many methods by which genome sequencing is currently performed, and advancements to the efficiency and cost-effectiveness of these methods are being updated as research becomes applicable.

Next-generation sequencing

Next-generation sequencing is the most current type of sequencing utilized. It is widely used due to its ability to sequence a large portion of the genome in a short amount of time, making it very useful and also cost-effective. With next-generation sequencing, an entire genome can be sequenced in roughly one hour. This type of sequencing is

used when a differential diagnosis is complex and an exact gene correlation is not known.

The reaction is done by extracting DNA from an individual (either through white blood cells or saliva), breaking the DNA down into fragments, and then amplifying the information via polymerase chain reactions. Whole genome sequencing and whole exome sequencing are also performed to ensure all pieces of the DNA are sequenced. This is done in millions of parallel sequences called multiplexing, as opposed to a single sequence done by older genome sequencing methods. Next-generation sequencing can also be more specific to certain genes or chromosomes as needed, depending on what the test is looking for. Because next-generation sequencing is still a new tool, more research is needed to validate its clinical efficacy. In addition, bioinformatics, computer technology, and trained personnel need to be available in order for this sequencing technique to reach its fullest clinical potential.

Sanger sequencing

Sanger sequencing was the previously preferred method of genome sequencing. It uses a strand of DNA, a polymerase chain reaction, a gel electrophoresis, and

KEY TERMS

DNA—Deoxyribonucleic acid, the main component in chromosomes and the substance that carries all genetic material.

Genetic code—A set of instructions for transferring genetic data stored in the form of DNA or RNA into proteins.

Genome—The entire genetic material of an organism.

Meiosis—The cellular process that results in the number of chromosomes in gamete-producing cells being reduced to one half and involves a reduction division in which one of each pair of homologous chromosomes passes to each daughter cell and a mitotic division.

Mitosis—A process that takes place in the nucleus of a dividing cell, typically a series of steps consisting of prophase, metaphase, anaphase, and telophase, and resulting in the formation of two new nuclei, each having the same number of chromosomes as the parent nucleus.

Nucleic acids—Any of various acids (such as DNA or RNA) that are found in living cells.

fluorescent tags on each of the four nucleotides to determine the order of nucleotides in the original strand of DNA.

Sanger sequencing is widely used when the differential diagnosis is being confirmed by genetic testing, typically after signs and symptoms are associated with a certain disorder. This is because Sanger sequencing can only sequence one DNA segment at a time, taking up to a few days to a few weeks to complete the sequence of one portion of the genome. It is not a good method to use when the genetic basis of a disorder is not narrowed down to a particular gene because it would take a lot of trial and error, and therefore time and money, to determine a genetic cause of a DNA using this method.

Genomic medicine

Definition

Genomic medicine involves personalizing health care and treatment based on each person's unique genetic makeup. Genomic medicine is also sometimes called personalized medicine, precision medicine, or individualized medicine.

Description

Historically, medical study focused on treating rather than preventing disease and was based on a one-size-fits-

KEY TERMS

Biomarker (biological marker)—A chemical, physical, or biological indicator that can be measured and can be used to assess health and disease.

Cell—Building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle, and connective tissue.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T), and cytosine (C). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The order of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid.

Gene—A sequence of bases in a DNA sequence that contains the instructions for a protein.

Genetic biomarker—A variant in DNA, RNA, or protein that can be measured and is an indicator of

disease. These biomarkers can be used to assess the expression, function, or regulation of a gene.

Genome—The complete set of genetic instructions of an organism.

Mitochondria—Structures found in the cell (organelles) surrounded by two layers of membrane. Mitochondria turn energy from food into energy that powers the cell. They also help the cell produce heat, store calcium, and choose which damaged cells need to be destroyed.

Mitochondrial DNA (mtDNA)—The DNA (genetic material) found in the mitochondria. MtDNA contains the instructions for about 37 genes. These genes produce proteins that help the mitochondria function. MtDNA is only passed from the mother to her offspring.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

RNA (ribonucleic acid)—The genetic material that is involved in creating proteins.

Variant—Change in the sequence of a genome.

all approach. This approach does not work for some people because common diseases are caused by a complex combination of genetic and environmental factors that vary among individuals. A study by the U.S. Food and Drug Administration (FDA) found that 38% to 75% of individuals with a common disease such as heart disease or diabetes do not significantly improve with treatment. One explanation is that medical treatment is based on statistical averages rather than on each patient's specific genetics.

Genomic medicine addresses this problem by personalizing treatment to each person's unique genotype. This approach holds promise for improving the quality of life, decreasing mortality, and reducing healthcare costs.

Genomic medicine has many benefits:

- predicting how susceptible a person is to a disease
- helping providers prescribe more effective drugs with fewer side effects
- increasing efficiency of pharmaceutical trials
- preventing disease rather than just treating it
- improving disease detection

- reducing the amount of trial and error involved in disease treatment

Examples of genomic medicine

Genetic testing

Genetic testing seeks the cause of a disease by looking for pathogenic variants (mutations) in DNA, RNA and in some cases mitochondrial DNA. Early genetic testing was based on symptoms and looked for large changes in chromosomes or variants in one or two genes. This approach is time-consuming and often does not yield results.

Subsequent approaches, such as whole genome sequencing and whole exome sequencing, helped to expedite a diagnosis and led to more effective treatment. Whole genome sequencing looks for variants in the whole genome. Whole exome sequencing looks for variants in the protein-coding parts of the genome that contain the genes.

Pharmacogenomics

Pharmacogenomics studies how certain gene variations affect the safety of certain medications and how well

they will work. Advances in this field have produced genetic tests that can help doctors choose the best medication and dose for each patient.

For example, variations involving the *CYP2D6* gene can influence the metabolism of codeine into morphine. Ultra-rapid metabolizers, people who have a duplicate of this gene, turn codeine into morphine faster and make greater amounts of morphine. They are at greater risk of having an overdose if they use codeine and may have serious problems as a result. Breastfeeding mothers with this variation who use codeine may provide excessive amounts of morphine to their baby and thus cause serious breathing problems in the infant and even death. People with another variant in *CYP2D6* do not metabolize codeine very well. Codeine does not work very well for these people, and they may need to use an alternative pain reliever.

Targeted drug therapies

Genomic medicine has helped researchers design targeted drug therapies based on genetic biomarkers. A genetic biomarker is usually a variant in DNA, RNA, or protein that can be measured and is an indicator of disease. Many targeted therapies based on the measurement of biomarkers have been developed to treat cancer. For example, 20% to 25% of women with breast cancer produce too much HER2 protein. This protein causes the tumor cells to grow more rapidly. HER2 is measured in women with breast cancer, and those with higher levels of this protein see improved outcomes if they are given the antibody trastuzumab along with their chemotherapy.

Gene therapy

Gene therapy involves treating a disease by adding, removing, or changing the genetic material in the cells of a patient. The transferred genetic material is typically DNA or RNA. DNA is genetic material that contains the genes that have the instructions for the production of proteins. Proteins are responsible for the structure and all the functions of our body and cells. RNA is the genetic material that carries out the instructions for the production

of proteins coded in the DNA. Gene therapy seeks to correct abnormal genes that are not functioning properly. The goal of gene therapy is to cure disease rather than just treat symptoms.

Using genomic medicine to prevent disease

Genomic medicine can help prevent disease by identifying those who would benefit from specific treatments before they have symptoms. For example, women with pathogenic variants in a *BRCA* gene have a high risk of developing breast and ovarian cancer. Prophylactic surgeries before the onset of symptoms, such as bilateral removal of the breasts (mastectomy) and ovaries, can reduce the risk of breast cancer by about 95%, the risk of ovarian cancer by 80%, and the risk of death by 68%.

Genotype and phenotype

Definition

The term “genotype” describes the actual set (complement) of genes carried by an organism. In contrast, “phenotype” refers to the observable expression of characters and traits coded for by those genes. Although phenotypes are based upon the content of the underlying genes composing the genotype, the expression of those genes in observable traits (phenotypic expression) is also, to varying degrees, influenced by environmental factors.

Description

The term “genotype” was first used by the Danish geneticist Wilhelm Johannsen (1857–1927) to describe the entire genetic or hereditary constitution of an organism. In contrast, Johannsen described displayed characters or traits (for example, anatomical traits, biochemical traits, physiological traits, etc.) as an organism’s phenotype.

Genotype and phenotype represent very real differences between genetic composition and expressed form. The genotype is a group of genetic markers that describes the particular forms or variations of genes (alleles) carried by an individual. Accordingly, an individual’s genotype includes all the alleles carried by that individual. An individual’s genotype, because it includes all of the various alleles carried, determines the range of traits possible (for example, an individual’s potential to be afflicted with a particular disease). In contrast to the possibilities contained within the genotype, the phenotype reflects the manifest expression of those possibilities (potentialities). Phenotypic traits include obvious observable traits as height, weight, eye color, hair color, etc. The presence or absence of a disease, or symptoms related to a particular disease state, is also a phenotypic trait.

A clear example of the relationship between genotype and phenotype exists in cases where there are

dominant and recessive alleles for a particular trait. Using a simplified monogenetic (one gene, one trait) example, a capital “T” might be used to represent a dominant allele at a particular locus coding for tallness in a particular plant, and the lowercase “t” used to represent the recessive allele coding for shorter plants. Using this notation, a diploid plant will possess one of three genotypes: TT, Tt, or tt (the variation tT is identical to Tt). Although there are three different genotypes, because of the laws governing dominance, the plants will be either tall or short (two phenotypes). Those plants with a TT or Tt genotype are observed to be tall (phenotypically tall). Only those plants that carry the tt genotype will be observed to be short (phenotypically short).

In humans, there is genotypic sex determination. The genotypic variation in sex chromosomes, XX or XY, decisively determines whether an individual is female (XX) or male (XY), and this genotypic differentiation results in considerable phenotypic differentiation.

Although the relationships between genetic and environmental influences vary (i.e., the degree to which genes specify phenotype differs from trait to trait), in general, the more complex the biological process or trait, the greater the influence of environmental factors. The genotype almost completely directs certain biological processes. Genotype, for example, strongly determines when a particular tooth develops. How long an individual retains a particular tooth is to a much greater extent determined by environmental factors such diet, dental hygiene, etc.

Because it is easier to determine observable phenotypic traits that it is to make an accurate determination of the relevant genotype associated with those traits, scientists and physicians place increasing emphasis on relating (correlating) phenotypes with certain genetic markers or genotypes.

There are, of course, variable ranges in the nature of the genotype-environment association. In many cases, genotype-environment interactions do not result in easily predictable phenotypes. In rare cases, the situation can be complicated by a process termed phenocopy, when environmental factors produce a particular phenotype that resembles a set of traits coded for by a known genotype not actually carried by the individual. Genotypic frequencies reflect the percentage of various genotypes found within a given group (population) and phenotypic frequencies reflect the percentage of observed expression. Mathematical measures of phenotypic variance reflect the variability of expression of a trait within a population.

The exact relationship between genotype and disease is an area of intense interest to geneticists and physicians, and many scientific and clinical studies focus on the

Genotypes and phenotypes: pedigree analysis chart (Gale)

relationship between the effects of genetic changes (for example, changes caused by mutations) and disease processes. These attempts at genotype/phenotype correlations often require extensive and refined use of statistical analysis.

Genotype tissue expression project (GTEx)

Definition

The genotype tissue expression project (GTEx) is an NIH Common Fund program with the purpose of examining the differences in how genes are expressed and regulated in different tissues of the body. The GTEx project was established with the goal of creating an information resource and associated tissue bank for scientific researchers.

Description

The GTEx project was established by the NIH (National Institutes of Health) in 2010 to address a gap in the knowledge of how genetic variation correlates with gene expression in multiple tissues. Previous studies using genome wide association studies (GWAS) had identified thousands of single nucleotide polymorphisms (SNPs) at chromosome locations within the human genome. A large number of SNPs have been linked to disease; however, because many SNP variants do not result in a change in the protein, the link between how specific SNPs effected changes in gene expression in a specific tissue or disease was not clear. To address this knowledge gap, the NIH funded the GTEx project with the goal of examining the link between tissue-specific gene expression and genetic variation. This included the development of a tissue bank for samples and the development of a website to function as a resource database.

By analyzing RNA expression levels as quantitative traits within individual tissues, variations in expression that are tightly linked with genetic variation will be identified as expression quantitative trait loci (eQTLs). SNPs that are correlated with gene expression level are known as eSNPs. Approximately 10% or more of gene transcripts are eSNPs located close to the gene (cis-eQTLs), while trans-eQTLs are those in which the eSNP is located far from the gene. The interpretation of GWAS study findings is one application of the identification of cis- and trans-eQTLs, which will create a foundation for studying gene regulation.

The primary goals outlined in the 2008 GTEx Workshop included development of coordination centers and storage locations, with the initial collection of tissues from 160 autopsy/transplant donors and 160 surgery patients to begin in 2010. Long-term goals of the GTEx project included the collection of tissues from an additional 900 donors over the following three years. During this process, a standard group of tissues (50–70 per autopsy donor) are collected and processed using

KEY TERMS

caHUB Acquisition of Normal Tissues—The Cancer Human Biobank, a section of which is dedicated to the storage of tissues for the GTEx project.

Donor Recruitment and Tissue Collection Centers (DRTCCs)—Several locations designated for identifying and enrolling donors and acquiring multiple tissue samples from each, using best practices for sample collection, handling, fixation, and storage.

Expression quantitative trait loci (eQTL)—Locations within the genomic loci that contribute to expression of mRNAs.

Gene expression—The process in which a gene is transcribed into mRNA, and then translated into a protein. Multiple methods of regulation are used by cells to tightly control the levels of gene expression.

Genome-wide association study (GWAS)—A study of common genetic variants between individuals to identify whether a variant is linked to a trait. Primarily used in assessing the link between SNPs and an associated disease.

Laboratory, Data Analysis, and Coordinating Center (LDACC)—The center designated for the coordination for the GTEx project, including sample processing and de-identification, database management, and eQTL analysis.

Single nucleotide polymorphisms (SNPs)—Single nucleotide variant (SNV); a variation or point mutation in a single nucleotide building block of DNA.

consistent methods. Collected tissues are then sent for processing at the Laboratory, Data Analysis, and Coordinating Center (LDACC).

The LDACC is responsible for the coordination of the overall GTEx project. These duties include:

1. Tracking and receiving samples and the de-identification of patient data.
2. Performing nucleic acid extraction and purification, genotyping, and RNA quantification by microarray and next-generation sequencing.
3. Performing statistical analyses to identify eQTLs.
4. Management and integration of all phenotypic and molecular data into the GTEx database at the National Center for Biotechnology Information (NCBI).
5. Organization of major GTEx activities, including working group meetings.

QUESTIONS TO ASK YOUR DOCTOR

- What information associated with my illness is available in the GTEx?
- If I were interested in donating tissues to the GTEx project, how would I proceed?
- What are the risks associated with tissue donation to GTEx?

The Cancer Human Biobank (caHUB) plays a key role in the GTEx project. The caHUB Acquisition of Normal Tissues in Support of the GTEx Project was a key initiative that allowed for the collection and storage of samples associated with the GTEx project. Additionally, the Brain Bank repository has provided the resources needed for the storage of brain tissue samples.

The data generated by the GTEx project have been designated by the NIH as a community resource. The majority of the data will be easily available through NIH resources on the Internet, with limitations placed on the accessibility of data that may impact donor identification. Some elements of the data that include sensitive identifiers will be accessible to the scientific community only through a controlled access system called the database of Genotypes and Phenotypes (dbGAP). As of 2015, research analyses were currently being published using data from 175 individual donors enrolled in the pilot study.

The GTEx project is a powerful tool for understanding the links between genetic variation and gene expression across many tissue types. The project provides a resource and a framework for understanding eQTLs in many tissues and will aid in the interpretation of GWAS findings in the ongoing research of many diseases.

Germline genome editing

Definition

Germline genome editing makes changes to the genetic material (genome) in eggs, sperm, or early embryos that can be passed down to future generations. The main goal of germline editing is to fix pathogenic (disease-causing) mutations and prevent genetic disease in offspring and future generations. Although considered unethical, it could also, potentially, be used to change characteristics of offspring such as height or intelligence.

Description

Early genome editing involved inducing mutations through radiation or chemical treatment in the laboratory. These techniques were not targeted and produced changes at random sites in the genome. The first experiments involving targeted editing of the genome were done on yeast and mice in the 1970s and 1980s. This early targeted editing was inefficient and could not be easily used in other species.

Many modern techniques of genome editing, which had their advent in the 2000s, rely on programmable (targeted) nucleases. Programmable nucleases cut DNA or RNA at a specific site and stimulate the desired change in the sequence. One of the most powerful genome editing techniques that uses programmable nucleases is CRISPR/Cas, a tool derived from the immune system of bacteria. CRISPR/Cas can be used to change an organism's DNA by making a cut in the DNA at a specific location and tricking the body's DNA repair mechanism to make the desired change. Doing so allows researchers to repair errors in the

sequence. Unfortunately, it can also cause unintended changes in the genome in other locations. Germline genome editing using CRISPR/Cas can result in a mosaic embryo, in which some cells are without the genetic change while other cells contain the genetic change. This effect can result in abnormalities in the embryo.

Genome editing can be performed in either somatic or germline cells. Somatic gene editing involves changing the genetic material in a tissue or cell other than sperm or egg cells. Somatic gene editing is often used to correct an error in the genetic material that results in a missing or abnormal protein. Somatic gene editing fixes that error so that a functioning protein is produced in the cells that are targeted. This can be done on cells outside the body that are transferred back to the patient or directly on cells in the body.

Somatic gene editing changes are not passed on to offspring. For example, in one trial, researchers removed cells from a patient who had a genetic variant (mutation) that caused the production of defective hemoglobin protein. Hemoglobin is used to transfer oxygen to the various parts of the body. Researchers corrected the variation in the removed cells that subsequently produced normal

hemoglobin. The repaired cells were then transferred back into the patient and produced normal hemoglobin. This treatment fixed the blood cells, but not the egg or sperm cells; it could, therefore, not be passed on to their offspring.

If the researchers had changed the hemoglobin variation in the egg or sperm cells or an early embryo, then this procedure would be called germline genome editing. These types of changes cause permanent changes in the individual and the person's offspring.

Germline genome editing can involve the transfer of mitochondrial DNA from a donor female to an egg cell. This technique can be used to improve fertility and fix errors in the mitochondrial DNA of offspring. Mitochondria are structures found in the cell that produce most of the energy needed to power the cell. Mitochondria contain mitochondrial DNA (mtDNA), which is only passed from the mother to her offspring. Although this technique has resulted in the birth of healthy children, it has also resulted in miscarriages and children with abnormalities.

Ethical issues

Germline genome editing performed in the laboratory rather than on humans can help researchers discover

how genetic variants affect disease and how they can be treated. In human medicine, germline genome editing has the potential to be a powerful tool to cure genetic disease and prevent its transmission to future generations.

There are, however, potential ethical concerns when germline editing is applied to humans:

- It could increase prejudice against people with genetic disease.
- It could be used to improve desirable traits rather than curing disease, which can have unintended societal consequences.
- It could result in unintended changes in the genome, which could cause cancer, genetic disease, and other problems.

An example of how germline genome editing can go wrong occurred in 2018 when Chinese scientists performed germline editing using CRISPR/Cas on twin girls to make them more resistant to HIV. Unfortunately, the gene variation introduced into the babies may also have made them and future generations more susceptible to other infections, such as influenza. This germline editing using CRISPR/Cas may also have introduced other unintended mutations. This experiment received international condemnation and renewed calls for an international moratorium on germline editing. The scientists involved were sent to prison and fined as a result.

Most scientists support a moratorium on using CRISPR/Cas for germline editing until more research is done and global ethical guidelines are developed. The United States has a moratorium on this type of germline editing, and it is banned in many other countries.

Germline mosaicism

Definition

Germline mosaicism occurs when some of the eggs or sperm have a different genetic makeup than others within the same organism. The term is often used to describe mosaicism for a pathogenic variant that causes disease and can be passed on to future offspring.

Description

Mosaicism happens after conception, and it results when only some cells of the body have a genetic variant and others do not. Humans start from one cell, which results from the fusion of an egg and sperm. This one cell, the zygote, normally contains 23 chromosome from the egg and 23 from the sperm. The chromosomes are made up of DNA packaged with protein, and contain the instructions for the development and functioning of the human body.

All the cells in the body are derived from this zygote and ideally should be identical copies. However, sometimes these cells are not identical copies because one of the cells acquires a genetic variant. If this happens, then all of the cells that come from this cell will have this variant. As of 2021, what causes this variant was unknown, but in some cases it may result from certain types of environmental exposure. Mosaicism happens if the variant occurs only in some of the cells of the body and not in others.

Germline mosaicism occurs when some of the reproductive (germline) cells have a genetic variant while others do not. If the variant originates in one of the germline cells, then the person will have isolated germline mosaicism, which does not affect the other cells of the body. Somatic mosaicism happens if the variant is found in some of the somatic cells, which are cells other than the egg or sperm cells and that are not involved in reproduction. If the variant happens early in embryonic development before the germline cells and somatic cells have separated into two different cell lines, then the person will have both somatic and germline mosaicism. If the variant

occurs in a somatic cell after the cell lines branch off, then the person will only have somatic mosaicism.

In some cases the variant is minor and does not cause disease. If it does cause disease, then it is called a pathogenic variant. In many cases when people refer to germline mosaicism, they are referring to a pathogenic variant.

Parents with germline mosaicism of pathogenic variants are at increased risk for having children with the genetic disease caused by the variant. The chances that this variant will be passed on to a child depend on how many germline cells have the variant and the type of condition. The number of affected germline cells cannot be measured. The recurrence risks range from 1% to 30%.

If an egg or sperm with the variant results in a zygote, then the resulting fetus will have the variant in all of its cells. The child will have inherited the genetic disease caused by the variant. This child will not have mosaicism, but will have a higher chance of passing the genetic disease on to offspring. People who only have somatic mosaicism are not at increased risk for having a child with the condition.

People with isolated germline mosaicism do not have symptoms since they do not have the pathogenic variant in any of their somatic cells. People with combined somatic and germline mosaicism may have symptoms of the disease. The severity of the symptoms depends on how many somatic cells have the variant. The symptoms that an individual with only somatic mosaicism will have depend on how many cells have the variant.

The frequency of germline mutations depends on the condition. Some conditions, such as Alport syndrome, which results in progressive kidney failure, seem to have a low rate of germline mosaic. Other conditions, such as some hemophilia and muscular dystrophies, have a relatively high germline mosaicism rate of 11% to 20% in cases in which the disease seems to originate in the child.

Germline mosaicism can be hard to detect, especially in women, and is often inferred if someone has multiple children with a variant that is not found in the blood cells of either parent. If the variant is present in enough sperm cells, then germline mosaicism can be confirmed through analysis of the sperm.

Examples

The variants in germline mosaicism are sometimes chromosome abnormalities. More commonly they are point mutations or small pieces missing or duplicated or added to the DNA. A point mutation is an error in the DNA sequence in which one DNA base is substituted for another or inserted or deleted.

Germline mosaicism usually occurs in autosomal dominant and X-linked disorders. An autosomal dominant disorder is caused by a pathogenic variant in one copy of a particular gene. This gene is found on one of the 22 autosomes, the non-sex chromosomes. Autosomal dominant conditions are inherited from one of the parents. Parents who have an autosomal dominant condition and do not have germline mosaicism have a 50% chance of passing the disease on to their offspring. The risk is lower for parents with germline mosaicism but hard to estimate.

An X-linked condition is caused by a pathogenic variant on the X chromosome. Females have two X chromosomes, and males have an X and Y chromosome. These are called the sex chromosomes. Females get one X chromosome from their mother and one from their father. Males get one X chromosome from their mother and one Y chromosome from their father. Males are affected when they inherit the gene variant from their mother. In most cases, a female who inherits a pathogenic variant in one copy of the gene that causes the X-linked condition does not have symptoms. She is called a carrier female. There are exceptions; some carrier females can have symptoms. Carrier females without germline mosaicism have a one-in-two (50%) chance that their sons will be affected and one-in-two (50%) chance that their daughters will be carriers. Daughters of affected males will be carriers, and sons of affected males will not be affected.

There have been rare case reports of germline mosaicism in autosomal recessive disorders. A person who has an autosomal recessive condition has a pathogenic variant (mutation) in both copies of a gene that causes this condition. This gene is found on one of the 22 autosomes. Their parents are each carriers of one variant. A carrier for an autosomal recessive genetic disease has a pathogenic variant (mutation) in one copy of a gene and one functioning copy of that same gene. Carriers often do not have symptoms because they have one functioning copy of the gene. Two carriers of an autosomal recessive condition who do not have germline mosaicism have a one-in-four (25%) chance of passing it on to their children.

Most cases of germline mosaicism (80%) happen in males. Germline mosaicism happens more frequently in sperm as male germline cells undergo many more cell divisions to produce sperm. This increases the likelihood that a variant will occur. Advanced paternal age seems to increase the risk of germline mosaicism.

Germline mosaicism in females is rarer. It is mainly seen in X-linked conditions such as Duchenne muscular dystrophy. Occasionally, autosomal dominant conditions

KEY TERMS

Autosomal dominant—Condition caused by a pathogenic variant (mutation) in one copy of a particular gene. Individuals with an autosomal dominant condition have a one-in-two (50%) chance of passing it on to their children.

Autosomal recessive—Condition caused by a pathogenic variant (mutation) in both copies of a particular gene. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

Carrier—Person who has a pathogenic variant in one copy of a gene that causes an autosomal recessive condition. Carriers often do not have symptoms. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

Cell—Building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle, and connective tissue.

Chromosome—The package of DNA found in each cell of the human body apart from the red blood cells. Humans have 22 pairs of autosomes (1 to 22) and one pair of sex chromosomes (XY). Females have two X chromosomes, and males have an X and Y. Normally, humans inherit one chromosome of each pair from their mother and one from their father.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T), and cytosine (C). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The order of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid.

Gene—A sequence of bases in a DNA sequence that contains the instructions for one protein.

Germ cells—The cells that create the egg and sperm cells (gametes).

Germline—Cells, including the egg, sperm, and fertilized egg that pass on their genetic material to the next generation of cells.

In vitro fertilization (IVF)—A form of assisted reproductive technology (ART) in which embryos are formed in the lab by combining eggs and sperm, culturing the embryos, and then transferring the embryos to the recipient's uterus.

Mosaicism—A condition in which a single multicellular organism has more than one genetic line in its cells as the result of genetic mutation.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Point mutation (DNA)—Error in the DNA sequence in which one DNA base is substituted for another or inserted or deleted.

Somatic cells—Cells of the body that are not involved in reproduction.

Variant—Change in the sequence of DNA.

X-linked—A condition caused by a pathogenic variant on the X chromosome. Most X-linked conditions are found in males who have one X chromosome and one Y chromosome. Females are less likely to have symptoms if only one of their X chromosomes has a pathogenic variant (mutation), since they have two X chromosomes.

result from female mosaicism. In most of these cases, the female has somatic mosaicism as well.

A parent who has no symptoms and has multiple children with an autosomal dominant or X-linked genetic condition might have germline mosaicism. For example, there is a case report of a healthy truck driver without symptoms who fathered three children with different mothers along his truck route in Brazil, with each of the children having the same genetic disease. Genetic testing discovered that all three half-siblings had the same pathogenic variant. The variant was not found in this man's

blood cells, indicating that he did not have the condition. Sequencing of his sperm cells, however, revealed that he had germline mosaicism.

Germline mosaicism is known to occur in female carriers of X-linked disorders such as alpha-thalassemia X-linked intellectual disability syndrome. This condition is characterized by severe intellectual disability, characteristic facial features, and mild anemia. Females with germline mosaicism for this condition have a variant for this disorder in some of their egg cells but not in their blood cells.

Giant congenital melanocytic nevus

Definition

Congenital melanocytic nevi (CMN) are pigmented skin growths that can vary in shape and size across the surface of the body. They are present at birth and can cover all regions of the body. CMN are also called birthmarks or moles. When they cover large areas of the skin, CMNs can be classified as giant melanocytic nevi.

Description

CMNs can present as light brown to black patches of various sizes on the skin. In extreme cases of giant CMNs, these patches can cover nearly the entire surface of the body. These nevi are present at birth and usually grow in proportion to the body size as the child develops. Those afflicted with giant nevi will likely have many smaller satellite nevi of various sizes that can develop during the first few years of life.

There are three forms of CMN: small-sized nevi that are less than two centimeters in diameter (0.78 in), medium-sized nevi that are greater than two centimeters but less than 20 centimeters (7.87 in) in diameter, and giant-sized nevi that are characterized by one or more large, darkly pigmented patches that are heterogeneous in composition and may have excess hair. A giant CMN is also referred to as a bathing trunk nevus, garment nevus, and giant hairy nevus.

Some congenital nevi may be light in color or not pigmented at all, but may develop over time into darker, more prominent nevi. CMNs can be superficial or span several layers of the dermis. They can also associate with neurovascular bundles, hair follicles, and subcutaneous fat cells. CMNs can resemble melanomas, but multiple benign nevi are characteristic of the congenital condition. Abnormal and normal melanocytes develop from populations of embryonic cells that also contribute to the development of the central nervous system. Giant CMNs can develop on the tissue covering the brain and spinal cord in an associated condition called neurocutaneous melanosis. The growth of CMNs in these tissues can put pressure on the brain and lead to symptoms such as headaches, seizures, mobility problems, and sometimes brain tumors.

Genetic profile

Congenital melanocytic nevus conditions are associated with somatic mutations in genes that are responsible for the regulation of protein signaling pathways associated with cell proliferation and development. Approximately four out of five cases are caused by mutations affecting the NRAS enzyme, and one in six cases are caused by mutations affecting the BRAF enzyme. Single mutations in these genes can cause abnormal and unregulated enzyme activity.

NRAS is a member of a family of genes that code for GTPase proteins. These proteins are important for the regulation of signaling pathways that mediate cell division and differentiation in a number of tissue types. BRAF is an enzyme called a serine/threonine protein kinase; these proteins are often involved in signaling cascade pathways that regulate cellular growth. GTPase proteins modulate kinase activity, and mutations in either a GTPase or a kinase can alter the ability of cells to divide, grow, and differentiate properly. In CMN, mutations in the *BRAF* or

KEY TERMS

Lesion—A defective or injured section or region of the brain (or other body organ).

Melanocyte—A cell that can produce melanin.

Melanocytic nevus—A nevus that contains pigmented skin cells called melanocytes. Melanocytic nevi are skin lesions that are also commonly described as moles.

Melanoma—Cancer that develops in melanocytes, the pigmented skin cells.

Nevus (plural, nevi)—Any anomaly of the skin present at birth, including moles and various types of birthmarks.

NRAS genes that make them constantly active in skin tissue can contribute to an overproduction of melanocytes.

Mutations in *NRAS* or *BRAF* are usually sporadic but can be inherited as autosomal dominant mutations. Multifactorial inheritance may contribute more to CMN occurrence than direct parental inheritance.

Demographics

Giant CMN occurs in 0.002% of births worldwide. It occurs in all races and genders equally.

Signs and symptoms

Symptoms of giant CMN include the presence of a large, darkly colored patch of skin, usually on the trunk of the body. CMN is present at birth, and additional nevi of various sizes can also be present or develop over the life of the individual. Nevi can be raised from the surface of the skin, have a different texture from other parts of the skin, and range from light brown to black in color. Most nevi do not cause any pain, although nevi that are associated with nerves can be sensitive or itchy. In rare cases, CMN can develop on brain and spinal cord tissues, which can complicate neurological function.

Diagnosis

Congenital nevi can resemble melanoma, and larger nevi are at a higher risk of being or becoming malignant. In fact, melanoma develops in 1%–2% of people with CMN, and at earlier life stages than those without CMN. Diagnosis of the various forms of CMN depends on clinical and dermoscopic features. Size, topology, extension into the dermis, and the association with nerves, hair follicles, and blood vessels are all part of diagnosing cases

QUESTIONS TO ASK YOUR DOCTOR

- Is nevus skin different from “normal” skin?
- What are the causes of CMN?
- Are there health concerns associated with CMN that I should be aware of?
- Are there treatment options that are reasonable for my condition?

of CMN. Biopsies can be taken to characterize the histological features of the nevi and also to check for cancerous growth. Oftentimes lifelong monitoring is necessary to check for any changes in the nevi.

Treatment and management

Removal of nevi is often considered to reduce chances of cancer development and also for aesthetic reasons. Some nevi are superficial and easy to remove; other nevi with extensions that reach into the deeper layers of the skin require more invasive surgical removal. Excess hair and some superficial pigmentation can be removed with the use of laser treatments. There are risks of scarring, pain during recovery, and recurrence with nevus removal, so it is not always acceptable in all cases of CMN.

Palliative treatment tries to address itching or other discomfort that is sometimes associated with larger nevi. Some commercial creams and lotions are available, but they do not work for everyone.

Prognosis

With the exceptions of having a higher risk of developing melanoma and some rare cases of neurological complications associated with CMN, it is not a life-threatening condition.

Glanzmann thrombasthenia

Definition

Glanzmann thrombasthenia (GT) is an extremely rare inherited disorder in which there is abnormal function of a component of the blood called the platelets, leading to abnormalities in blood clotting and increased bleeding.

Description

Blood clotting, or coagulation, is the process by which several factors in the blood stick together to form a physical barrier that prevents bleeding. In response to a disruption in blood flow or bleeding because of injury, several factors in the blood clump together at the site of injury, sealing off the blood vessel and stopping blood loss in a process called hemostasis. If any of the factors that contribute to the process of coagulation and hemostasis are abnormal, dangerous bleeding conditions can result.

One of the factors involved in hemostasis is called the platelet. Platelets are small disc-shaped structures that circulate in the blood stream in an inactive state. When an injury occurs, platelets become activated and stick to fibrous proteins, called fibrinogen, that are also circulating in the blood stream. Because there are multiple sites on the fibrinogen proteins for platelets to bind, and vice versa, a cross-linked net or mass called a platelet plug is formed, which seals off the injury and prevents further bleeding. Next, the platelet mass actively contracts to form an even more solid mass in a process called clot retraction. Over time, repair cells can use this mass as a

scaffolding to lay down new tissue and thereby effect a permanent repair of the injury.

Platelets attach to fibrinogen through the use of specialized sugar proteins (glycoproteins) that are present on the platelet surface. There are two specific glycoproteins that form a complex responsible for the platelet-fibrinogen interaction: glycoprotein IIb and glycoprotein IIIa.

The platelet disorder GT results from an inherited defect in the glycoprotein IIb/IIIa complex (GP IIb/IIIa). As a result of this glycoprotein defect, platelets fail to stick to fibrinogen, leading to defective hemostasis and prolonged bleeding. GT is sometimes subdivided into different groups: type I, in which there is no functional GP IIb/IIIa; type II, in which small amounts of working GP IIb/IIIa can be detected; and variant thrombasthenia, in which the amount of working GP IIb/IIIa may vary. Glanzmann thrombasthenia has also been referred to by other names including thrombasthenia of Glanzmann and Naegeli, diacyclothrombopathia IIb-IIIa, Glanzmann disease, and glycoprotein complex IIb/IIIa deficiency.

GT was first described by the Swiss physician Edward Glanzmann in 1918. Glanzmann used the term “thrombasthenia,” meaning “weak platelets,” because clots from patients with the disorder did not retract well. Although the disease is exceedingly rare, platelets taken from people with the disease have been very useful in the research that first discovered how normal platelets function.

Genetic profile

GT is a genetic condition and can be inherited or passed on in a family. The disorder results from any number of different mutations that can occur in either the gene for glycoprotein IIb or the gene for glycoprotein IIIa (*ITGB3* and *ITGA2B*, both located on chromosome 17, locus 17q21.32), with defects split equally between the two genes.

In the majority of cases, it appears that the genetic abnormality for the disorder is inherited as an autosomal recessive trait, meaning that two abnormal genes are needed to display the disease. A person who carries one abnormal gene does not display the disease and is called a carrier. A carrier has a 50% chance of transmitting the gene to his or her children, who must inherit one abnormal gene from each parent to display the disease. People who are carriers of the abnormal gene appear to have only half-normal amounts of working GP IIb/IIIa, which is still sufficient for normal platelet function.

There are reports of a few families in which the defect is inherited in an autosomal dominant fashion. In this pattern of inheritance, only one abnormal gene is

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Coagulation—The process by which a liquid becomes a solid, as in blood clotting.

Fibrinogen—A fibrous protein that circulates in blood and participates in blood clotting by attaching to platelets.

Glycoprotein IIb/IIIa (GP IIb/IIIa)—Sugar proteins on the surface of platelets that bind to the fibrous protein, fibrinogen. These sugar proteins are defective in Glanzmann's thrombasthenia.

Hemostasis—The arrest of bleeding by blood coagulation.

Mutation—A change in the genetic material that may alter a trait or characteristic of an individual or manifest as disease.

Platelets—Small disc-shaped structures that circulate in the blood stream and contribute to blood clotting.

Transfusion—The injection of a component of the blood from a healthy person into the circulation of a person who is lacking or deficient in that same component of the blood.

needed to display the disease, and the chance of passing the gene to offspring is 50%.

Demographics

GT is exceedingly rare, with fewer than 1,000 cases identified. There are several groups in which the majority of cases of thrombasthenia have been discovered, including Iraqi Jews, Arabs living in Israel and Jordan, populations of south India, and French Gypsies of the Manouche tribe.

Signs and symptoms

Most people with GT will have a major bleeding event before the age of five. Common manifestations of the disease include nosebleeds, bleeding from the gums,

or skin rashes caused by bleeding into the skin (known as purpura or petechiae). Larger amounts of bleeding into underlying tissue may result in diffuse black bruises, usually seen on the arms and the legs. Normal handling of infants can cause superficial bruises and may be mistaken for abuse. As a result of chronic bleeding, patients may have lower amounts of red blood cells in their blood (anemia) and suffer from iron deficiencies. Rarely, there may be bleeding into the joints, causing disfigurement. Bleeding after traumatic accidents or after surgical operations and dental procedures may be profuse and require vigorous medical treatment. Prolonged untreated or unsuccessfully treated bleeding associated with GT may be life-threatening. For reasons that are unclear, severity of bleeding events appears to decrease with increasing age.

There are other concerns when GT is diagnosed in a woman. Because of the platelet disorder, women may experience particularly heavy menstrual bleeding. In fact, the first occurrence of menstrual bleeding in a young woman may be so severe that it requires prompt medical attention and treatment. Further, pregnancy and delivery represent severe bleeding risks and may not always be manageable with medical treatment.

Diagnosis

Glanzmann thrombasthenia is diagnosed through a combination of medical history, physical examination, and laboratory testing. Bleeding episodes and physical manifestations of the disease may prompt an investigation for the underlying cause. The presence of a bleeding disorder in more than one close or distant relative is especially important, as it may indicate that a genetic cause of the condition is involved.

Blood tests will reveal normal amounts of platelets. Tests performed with substances that stimulate platelet clumping though GP IIb/IIIa will show minimal effects as a result of the platelet defect. Conversely, tests performed using a different substance, ristocetin, which causes platelet clumping through different mechanisms, will provoke a brisk and appropriate platelet response. Other blood tests will reveal a longer than normal bleeding time, poor clot retraction, and may demonstrate low numbers of red blood cells and iron deficiency.

The diagnosis of GT is ultimately confirmed by investigating the GP IIb/IIIa glycoprotein complex. Antibodies that are specifically designed to distinguish between normal and abnormal GP IIb/IIIa can be used in a technique known as immunofluorescence (in which the antibody is attached to a fluorescent dye) or a test called a Western blot (in which proteins are first separated by size and then exposed to antibodies). These methods can also be used to detect people who are carriers of a mutant gene for GT by demonstrating only

half-normal amounts of GP IIb/IIIa. Prenatal diagnosis may also be possible but is not recommended as sampling of the blood in an affected fetus may lead to uncontrollable bleeding that could prove fatal.

Molecular genetic testing for both genes associated with GT is available as of 2021 from the Institute of Human Genetics in Germany. The test can be done on fibroblasts, peripheral whole blood, isolated DNA, or a white blood cell prep.

Treatment and management

Several medications can aid in the treatment of GT, while others should be avoided. Some patients will demonstrate shortening of their bleeding time with DDAVP, a medication that improves the function of platelets. Women who have heavy bleeding may benefit from birth control pills to prevent their menstrual periods. Nutritional iron supplements may alleviate or prevent the development of iron deficiency and will aid in restoring normal levels of red blood cells. Medications to be avoided are those that interfere with platelet function and predispose to bleeding, including aspirin, ibuprofen and ibuprofen-like drugs, heparin, warfarin, ticlopidine, clopidogrel, abciximab, streptokinase, urokinase, or tissue plasminogen activator.

The treatment of choice for stopping active bleeding is through transfusion of normal platelets that are obtained from donors without the disease. Studies have shown that most people (approximately 85%) with the disorder will require platelet transfusions during their lifetime. For individuals with GT, transfusion with one unit of platelets for every 11–22 lb. (5–10 kg) of body weight will correct the defect in blood clotting and may be life-saving. Pre-emptive transfusions are especially important before surgical operations or dental procedures. Transfusions should be continued until wound healing is complete.

Over time, platelet transfusion may become less effective. Platelets obtained from donors and given to a patient with GT are recognized by the immune system as foreign

cells. The immune system, in turn, generates antibodies that attach to the donor platelets and impair their function, ultimately leading to their destruction. Because of this unfortunate effect, platelet transfusions are best reserved for life-threatening bleeding or before procedures in which bleeding is likely. Using platelets from donors closely related to the patient may delay the immune response and extend the benefits of transfusion therapy.

Patients with GT should be followed closely by a hematologist, and should be vaccinated against the hepatitis B virus because of the high risk of exposure to the virus with ongoing blood-product transfusions. Patients should also be seen regularly by a dentist to prevent gum disease that could result in profuse bleeding. Genetic counseling can be offered to affected individuals or couples with a family history of the disorder.

Bone marrow transplantation is currently the only curative form of treatment for patients with GT. However, this is generally considered more hazardous than the disease itself, except in exceptional circumstances.

Prognosis

Although there is no cure, the prognosis for people with Glanzmann thrombasthenia is quite good. Despite the fact that the majority of people with this disorder will require medical treatment to control bleeding, patients rarely die of massive blood loss. Interestingly, the severity of bleeding appears to decrease with increasing age. Barring any catastrophic accident that results in uncontrollable bleeding, lifespan is approximately the same as the general population.

Glaucoma

Definition

Glaucoma is a group of eye disorders that result in vision loss due to a failure to maintain the normal fluid balance within the eye. If fluid pressure builds up, damage to the optic nerve occurs, leading to vision loss. If detected in its early stages, vision loss can be prevented through the use of medications or surgical procedures that restore the proper fluid drainage of the eye. Glaucoma usually develops in older adults; however, early-onset glaucomas—primary congenital glaucoma (PCG) and juvenile open-angle glaucoma—are genetic disorders, and susceptibility genes have been identified for adult forms of glaucoma.

Description

Vision is an important and complex sense by which the qualities of an object, such as color, shape, and size, are perceived through the detection of light. Light that bounces off an object first passes through the cornea (outer layer) of the eye and then through the pupil and the lens, where it is projected onto a layer of cells at the back of the eye called the retina. When the retina is stimulated by light, signals pass through the optic nerve to the brain, resulting in a visual image of an object.

The front chamber of the eye is bathed in a liquid called the aqueous humor. This liquid is produced by a nearby structure called the ciliary body and is moved out of the eye into the bloodstream by a system of drainage canals known as the trabecular meshwork. The proper amount of fluid within the chamber is maintained by a balance between fluid production by the ciliary body and fluid drainage through the trabecular meshwork. When fluid accumulates in the front chamber, either because of an overproduction of fluid or because of a failure of the normal drainage routes, fluid pressure builds up within the eye. Over time, this increased fluid pressure causes damage to the optic nerve, resulting in progressive visual impairment. Increased eye fluid pressure leading to vision loss is known as glaucoma.

Close-up of the eye of a patient suffering from glaucoma, where the lens of the eye is peeling away from the iris; this pseudo-exfoliation is seen as grey within the pupil. Glaucoma is caused by a structural abnormality in the drainage angles of the eyes. (Sue Ford/Science Source)

Glaucoma is a group of many different eye disorders that can manifest alone; as a sign of more than 60 different diseases; or as a result of an injury to the eye. Glaucoma can also be classified by the age of the affected individual: infantile or congenital glaucoma affects infants at birth or children up to three years old; juvenile glaucoma affects individuals from age three to 30; and adult glaucoma affects people older than 30.

Types of glaucoma

The National Eye Institute (NEI) defines five types of glaucoma according to the abnormality in the eye drainage system:

- **Open-angle glaucoma.** This is the most prevalent type of glaucoma. It occurs when the eye drainage passage is narrowed but still open. The narrowing of the passage increases intraocular pressure (the pressure inside the eye), damaging the optic nerve. Juvenile open-angle glaucoma is a primary glaucoma that develops during childhood or early adulthood and is caused by a genetic mutation.
- **Low-tension or normal-tension glaucoma.** In this type of glaucoma, the intraocular pressure is normal, but optic nerve damage and narrowed side vision occur.
- **Angle-closure glaucoma.** This type of glaucoma is a medical emergency. The fluid at the front of the eye cannot reach the angle and leave the eye, because the angle is blocked by part of the iris. People with this type of glaucoma have a sudden increase in intraocular pressure.
- **PCG.** Children with this genetic condition are born with a defect in the angle of the eye that slows the normal

Collateral vessels of the optic disc in a glaucoma patient.
(Paul Whitten/Science Source)

drainage of fluid. It is also called childhood, pediatric, or infantile glaucoma.

- **Secondary glaucomas.** These glaucomas can develop as complications of other medical conditions. They can sometimes result from eye surgery, advanced cataracts, eye injuries, certain eye tumors, or uveitis (eye inflammation).

Genetic profile

Glaucoma usually develops in older adults, but abnormalities that impede fluid drainage in the eye may be present at birth (congenital glaucoma), with early onset of symptoms by about five years of age (juvenile glaucoma). Genome wide association studies have identified more than 125 genetic locations (loci) with gene mutations that can cause different types of glaucoma, and at least nine of the genes themselves have been identified.

There are at least eight mapped gene loci for open-angle glaucoma, and two of these genes (*MYOC* and *CYP11B1*) account for a fraction of cases. Approximately 10% to 33% of people with juvenile open-angle glaucoma have mutations in the *MYOC* gene. *MYOC* mutations can also result in primary congenital glaucoma (PCG). The *MYOC* gene provides instructions for producing a protein called myocilin that is found in the trabecular meshwork and the ciliary body of the eye that regulates the intraocular pressure. It is believed that defective myocilin may accumulate in the trabecular meshwork and ciliary body, thus preventing the flow of fluid from the eye and causing the increased intraocular pressure of glaucoma. Research has also shown that 20% to 40% of people with PCG and some people with

juvenile open-angle glaucoma have mutations in the *CYP11B1* gene. This gene provides instructions for producing a form of the cytochrome P450 protein found in the trabecular meshwork, the ciliary body, and other structures of the eye. Defects in the *CYP11B1* protein may interfere with development of the trabecular meshwork and/or regulation of fluid secretion from the inside of the eye. Other research has shown that the protein may interact with myocilin. Individuals with mutations in both the *MYOC* and *CYP11B1* genes may develop earlier-onset glaucoma and have more severe symptoms.

Mutations in other genes also appear to be involved in congenital or early-onset glaucoma. Mutations in the *LTBP2* gene, encoding latent-transforming growth factor beta-binding protein 2, can cause PCG. Two other loci also have been linked to PCG.

Glaucoma can be inherited in either an autosomal recessive (PCG) or an autosomal dominant manner (juvenile open-angle glaucoma). In autosomal recessive inheritance, two abnormal genes are needed to cause the disease. A person who carries one abnormal gene does not have symptoms of the disease and is known as a carrier. A carrier has a 50% chance of transmitting the gene to a child, who must inherit one abnormal gene from each parent in order to develop the disease. Alternately, in autosomal dominant inheritance, only one abnormal gene is needed to develop the disease, and the chance of passing the gene and the disease to offspring is 50%. PCG is also inherited in an autosomal dominant pattern in some families. The presence of two mutated *CYP11B1* genes increases the risk of severe disease and glaucoma in both eyes and is linked to a family history of PCG as well as parental consanguinity (relatedness). If the mutations (pathogenic variants) have been identified in the parents or other affected family members, prenatal diagnosis and carrier testing are available for *CYP11B1* and *LTBP2* mutations. Genetic testing is also available for *CYP11B1* and *MYOC* mutations that cause open-angle juvenile glaucoma.

Other gene variants associated with the development of primary open-angle glaucoma (POAG) include *SVEP1*, *RERE*, *VCAM1*, *ZNF638*, *CLIC5*, *SLC2A12*, *YAP1*, *MXRA5*, and *SMAD6*.

Demographics

Glaucoma is the leading cause of preventable blindness in the United States and the third leading cause of blindness worldwide. It can develop at any age, but people over 45 are at higher risk. The prevalence of glaucoma increases with advancing age, reaching 10%

Types of glaucoma and related genetic information (Gale)

in persons age 90 and older. Primary congenital glaucoma (PCG) affects approximately one in 10,000 people. The frequency is higher in the Middle East. Juvenile open-angle glaucoma affects about one in 50,000 people. Primary open-angle glaucoma (POAG) affects about 1% of the population over age 40. Asians are more prone to angle-closure glaucoma, as are the Inuit in Canada and Greenland.

Signs and symptoms

In the adult and juvenile forms of open-angle glaucoma, vision loss begins at the periphery (outer edges) of

the visual field, resulting in tunnel vision. Because the visual loss is not in the individual's central vision, he or she might not notice this change. However, if the glaucoma is left untreated, loss of vision progresses, and central vision is often affected, sometimes resulting in blindness. The average time from development of high eye fluid pressure to the appearance of visual loss is 18 years in the adult form, but much shorter in the juvenile form.

In contrast to the adult and juvenile forms, congenital or infantile open-angle glaucoma is noted at birth or within the first three years of life. Symptoms include cloudy corneas, excessive tearing, and sensitivity to light.

Glaucoma is an eye disease in which increased fluid pressure in the eye causes damage to the optic nerve. Glaucoma will damage vision or cause blindness if left untreated. If the condition is detected early enough, it is possible to halt or arrest the progression of the disease.
(Spencer Sutton/Science Source)

Because the eye is very flexible in infants, increased fluid pressure may cause bulging of the eye (buphthalmos or “ox eye”). Children with glaucoma in only one eye are usually diagnosed earlier because a difference in eye size is noticeable. When the disorder affects both eyes, many parents view the large eyes as attractive and do not seek medical help until other symptoms develop, delaying the diagnosis.

With angle-closure glaucoma, symptoms come on suddenly. People may experience blurred vision, severe pain, headache, sensitivity to light, and nausea. The development of this type of glaucoma is an emergency and requires immediate treatment.

Diagnosis

The diagnosis of glaucoma may be suggested by certain physical findings, especially in infants, but it is confirmed by tests with special instruments. Parents may bring their young infant to a physician if they notice changes in the eye shape and size, both of which are signs of infantile glaucoma. Diagnosis of PCG and open-angle juvenile glaucoma may be confirmed with genetic testing.

In adults who do not show obvious signs of glaucoma, the condition is frequently detected by routine eye exams and other tests. Using an ophthalmoscope (a handheld or machine-mounted instrument with a light

source), a physician or optometrist will look through the pupil to the back of the eye. There, he or she may detect characteristic changes in the region where the optic nerve meets the eye, called the optic disk.

In another portion of a routine eye exam, an ophthalmologist or optometrist will measure the fluid pressure of the eye through the use of a special instrument called a tonometer. The test is painless and involves brief contact of a small probe with the surface of the eye. Presence of elevated pressure (more than 21 mm Hg) means that a person is at risk for glaucoma.

Once high pressure or changes in the optic disk are noted, an ophthalmologist can also use a gonioscope (a small lens with a reflecting mirror) to inspect the drainage passageways of the eye and determine whether they are blocked. Visual field tests (in which individuals indicate whether they can see small flashing lights that are directed at different spots in their visual field) are used as a final indicator for the presence of glaucoma or a measurement of how far glaucoma-related visual loss has progressed.

Treatment and management

Although there is no treatment for the optic nerve injury and vision loss caused by glaucoma, it is possible to prevent further visual loss by lowering eye fluid pressure. In adults, this is primarily achieved through medications, which can reduce eye fluid pressure by either decreasing fluid production or increasing fluid drainage from the eye. The medications can be taken orally (by mouth) or applied to the eye through drops. The different classes of medications used to treat glaucoma include beta-blockers, alpha agonists, carbonic anhydrase inhibitors, and prostaglandin analogues.

For infantile glaucoma, the treatment is usually surgical. Laser surgery or microsurgery to open the drainage canals can be effective in increasing drainage of eye fluid. Other types of surgery can be performed to reduce the amount of fluid production. Many children require several operations to lower or maintain their eye fluid pressure adequately, and long-term treatment with medications may be necessary.

For angle-closure glaucoma, immediate hospitalization and treatment with medication is required. Once the person’s condition has been stabilized, laser surgery is used to create a passageway for fluid drainage.

All individuals with glaucoma should see an ophthalmologist regularly to evaluate progression of the condition and whether it is being adequately treated. Beginning at the age of 40, all people should have regular screening exams to detect early signs of glaucoma.

KEY TERMS

Angle-closure glaucoma—An increase in the fluid pressure within the eye due to a complete and sometimes sudden blockage of the fluid-drainage passages.

Aqueous humor—Fluid produced by the ciliary body and contained within the front chamber of the eye.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a non-sex chromosome is required for a disease or inherited trait to develop in an individual.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Buphthalmos—A characteristic enlargement of one or both eyes associated with infantile glaucoma.

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Ciliary body—A structure within the eye that produces aqueous humor.

Cornea—The transparent structure of the eye over the lens that is continuous with the sclera in forming the outermost, protective layer of the eye.

Gonioscope—An instrument used to examine the trabecular meshwork; it consists of a magnifier and a lens equipped with mirrors.

Open-angle juvenile glaucoma—Hereditary glaucoma that develops in childhood or early adulthood

and can be caused by mutations in the *MYOC* or *CYPB1* genes.

Ophthalmologist—A physician specializing in the medical and surgical treatment of eye disorders.

Ophthalmoscope—An instrument with special lighting designed to view structures in the back of the eye.

Optic disk—The circular area at the back of the eyeball where the optic nerve connects to the retina.

Optic nerve—A bundle of nerve fibers that carries visual messages from the retina in the form of electrical signals to the brain.

Optometrist—A medical professional who examines and tests the eyes for disease and treats visual disorders by prescribing corrective lenses and/or vision therapy. In many states, optometrists are licensed to use diagnostic and therapeutic drugs to treat certain ocular diseases.

Primary congenital glaucoma (PCG)—Glaucoma that is present at birth or develops during the first year of life and can be caused by mutations in the *CYPB1* or *LTBP2* genes.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Tonometer—A device used to measure fluid pressures in the eye.

Trabecular meshwork—A sponge-like tissue that drains the aqueous humor from the eye.

People with a family history of glaucoma or with diabetes should be screened beginning in young adulthood.

Promising research

In 2021, researchers from Santen Inc., Massachusetts Eye and Ear, and Ulster University announced the formation of a global research initiative to study and develop new treatments for glaucoma. Research will focus on ways to preserve vision by preventing, slowing, or reversing damage caused by glaucoma. The same year, another international collaboration between the Moscow Institute of Physics and Technology and Harvard Medical School reported the first successful attempt to grow and transplant retinal ganglion cells, specialized neurons that are damaged in glaucoma, developed from stem cells.

Retinal ganglion cells are responsible for transmission of visual information. Although this first attempt was an animal study, researchers hope that this technology will be ready for use in humans in about 10 years.

Clinical trials

Clinical trials on glaucoma are sponsored by the National Institutes of Health (NIH) and other agencies. As of 2021, the NIH listed 245 recruiting, ongoing, and active clinical trials for PCG. Clinical trial information is continually updated.

Prognosis

Since even small degrees of vision loss due to glaucoma cannot be reversed, early detection of the condition

QUESTIONS TO ASK YOUR DOCTOR

- Which type of early-onset glaucoma does my child have?
- What is the inheritance pattern for early-onset glaucoma?
- Should we have genetic testing for genes that cause glaucoma?
- What is our risk of having another child with early-onset glaucoma?
- Is prenatal testing available for early-onset glaucoma?

through regular eye examinations is critical. If glaucoma is detected early, lifelong medical treatment can halt the progress of the disease and maintain relatively normal vision. If left undiagnosed or untreated, many people with glaucoma progress to blindness.

Angle-closure glaucoma is an emergency, and the prognosis depends on the severity of the attack and how quickly medical attention is obtained. Left untreated, the condition can quickly lead to total vision loss in the affected eye.

Glycine encephalopathy

Definition

Glycine encephalopathy is a genetic disorder that results from too much of the amino acid glycine in the body tissues, including the brain.

Description

Mutations in either of two genes can cause glycine encephalopathy. Mutations in one of the genes, known as the glycine dehydrogenase (decarboxylating) or *GLDC* gene, cause more than four-fifths of all cases. Another 10%–15% of cases result from mutations in the other gene, called the aminomethyltransferase, or *AMT* gene. The remaining 5%–10% of cases may have other causes, including mutations in a gene known as the glycine cleavage system protein H (aminomethyl carrier), or *GCSH*.

GLDC and *AMT*, the two main genes related to glycine encephalopathy, carry the instructions for making enzymes that are an important part of the mechanism involved in breaking down glycine. Glycine is an amino acid (a building block of proteins) that is also very important in the transmission of nerve impulses.

When one of these genes is defective, glycine does not break down as it should. Instead, it accumulates in tissues and organs, notably the spinal cord and brain, where it can be toxic. When this buildup occurs, the person may experience symptoms such as intellectual disability and seizures.

There are four forms of glycine encephalopathy:

- classical (or neonatal), in which symptoms appear soon after birth (the most common form of the disease)
- infantile, which usually develops when the infant is about six months old
- late onset, which may have severe and rapidly progressing symptoms
- transient glycine encephalopathy, in which glycine levels are high at birth but return to normal or near-normal later on, and which has few or no symptoms

Glycine encephalopathy is also called nonketotic hyperglycinemia (NKH).

Genetic profile

Most cases of glycine encephalopathy result from mutations in the *GLDC* or *AMT* genes, both of which lead to an overproduction of glycine. Glycine encephalopathy is an autosomal recessive disorder, which means that a child must inherit one copy of the mutated gene from each parent. The parents may not have the condition

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Glycine—An amino acid (a building block of proteins) that is important in the transmission of nerve impulses.

Hypotonia—Low or poor muscle tone, resulting in floppy limbs.

Lethargy—Fatigue.

Neurotransmitter—Chemical in the brain that transmits information from one nerve cell to another.

Nonketotic hyperglycinemia (NKH)—Glycine encephalopathy.

Vertical gaze palsy—Uncontrolled up and down motions of the eye.

themselves but may only be carriers of the mutation. Carriers are individuals who do not develop a disorder but may pass the gene for the disorder on to their children. If both parents are carriers, each of their children has a 50% chance of being a carrier and a 25% chance of having the disorder. If both parents have glycine encephalopathy, all of their children will have the disorder.

The *GLDC* gene is located on chromosome 9, and the *AMT* gene is located on chromosome 3. The *GLDC* gene carries the instructions for making an enzyme called glycine dehydrogenase, and the *AMT* gene holds the blueprint for making an enzyme called aminomethyltransferase. These two enzymes are part of an enzyme complex known as the glycine cleavage system that works in mitochondria (the powerhouses of cells) to break down glycine. Normally, the brain has enough glycine to help transmit signals within the central nervous system. When an individual inherits a mutated *GLDC* or *AMT* gene from both parents, glycine does not break down properly. As a result, excess glycine builds up to the point that it interferes with the normal transmission of nerve signals.

Not all *GLDC* or *AMT* mutations are the same. Scientists know of more than a dozen different mutations in the *AMT* gene and more than 40 mutations in the *GLDC* gene that can lead to glycine encephalopathy. Mutations may include the following:

- substitutions of amino acids
- insertion of added genetic material into the gene
- removal of some genetic material from the gene

QUESTIONS TO ASK YOUR DOCTOR

- Based on the symptoms in the early stages of late-onset glycine encephalopathy, how can the mild episodic form be distinguished from the rapidly progressing form?
- Is it possible to increase the dosage of sodium benzoate to improve its effects?
- What are the side effects, if any, of sodium benzoate?
- What scientific evidence, if any, is available that demonstrates that sodium benzoate can help improve mental development?
- Is genetic testing available for the mutations that cause glycine encephalopathy?

Depending on the specific mutation, the glycine dehydrogenase or aminomethyltransferase may not function at all or may function in a reduced capacity.

GCSH, the gene associated with much rarer mutations related to this disorder, is located on chromosome 16 and is also part of the glycine cleavage system.

Demographics

The overall prevalence of glycine encephalopathy is unknown. Studies in Finland and in British Columbia, Canada, however, have indicated an incidence in newborns of between 1 in 55,000 and 1 in 63,000. The British Columbia study also estimated a carrier frequency of about 1 in 125.

Both male and female children are affected with the disorder at similar frequencies, but males with the classical type have milder symptoms and a higher survival rate than females with the classical type. The reason for this disparity is unknown.

Signs and symptoms

Symptoms associated with the classical type of glycine encephalopathy may include the following:

- progressive lethargy
- poor muscle tone (hypotonia)
- difficulty breathing, sometimes severe or even life-threatening
- feeding problems
- jerking of the muscles, sometimes leading to a failure of respiratory muscles and death

- severe intellectual disability
- seizures
- coma

Symptoms associated with the infantile form may include the following:

- delayed development beginning at about six months of age
- seizures
- intellectual disability that develops over time
- behavioral problems

Symptoms associated with the late-onset form may be severe and worsen rapidly. They include the following:

- spasms and weakness of the legs
- degeneration of the optic nerve that connects the eye to the brain and helps produce vision
- mild intellectual disability
- abnormal movements of the body (choreoathetosis)

Among individuals with transient glycine encephalopathy, many show no effects from the temporarily high glycine levels and go on to live normal lives. In some cases, however, patients with this form of the disease may experience seizures and some level of mental disability even after their glycine levels drop to normal or near-normal. Other symptoms that occur in some patients include the following:

- sporadic episodes of abnormal body movements
- uncontrolled up and down motions of the eye (vertical gaze palsy)

Diagnosis

Examination

A doctor may suspect glycine encephalopathy if the patient has the set of symptoms described here. To form a diagnosis, however, the doctor will order tests.

Tests

Common tests for glycine encephalopathy are urine, cerebrospinal fluid, and/or blood analyses, which can identify high levels of glycine. Genetic screening may detect mutations in the *GLDC*, *AMT*, and/or *GCSH* genes. Newborns may be screened for glycine encephalopathy.

Treatment and management

No cure exists for glycine encephalopathy. Treatments are directed at specific symptoms.

Traditional

Various treatments may be available to ease certain symptoms. For instance, physical therapy may assist with hypotonia.

Drugs

Sodium benzoate may help decrease the glycine overload. It may also help reduce convulsions and improve behavioral problems in some individuals. The doctor may prescribe anticonvulsant medications to treat seizures. Studies are continuing on the use of other drugs for the treatment of symptoms such as decreased brain activity and delayed development.

Prognosis

People with classical glycine encephalopathy often have severe breathing difficulties, among other symptoms, and frequently die soon after birth. The infants that do survive initial breathing problems and begin to breathe on their own usually have profound intellectual disability as well as repeated seizures that are hard to control even with anti-seizure drugs.

Individuals with the infantile form of glycine encephalopathy have milder, sometimes remittent symptoms, but they typically experience at least moderate intellectual disability as the years go by. This form, as well as the mild-episodic and the rapidly progressing late-onset forms of the disorder, are so rare that prognosis is given on a case-by-case basis.

Glycogen storage diseases

Definition

Glycogen is a form of stored glucose that the body uses as an energy source. Glycogen storage disease (GSD) involves defects that cause an abnormal accumulation of glycogen, usually found in the liver, muscle, or both. When accumulation occurs in the liver, glycogen storage diseases result in liver enlargement and in conditions ranging from mild hypoglycemia to liver failure. When the accumulation occurs in muscle, glycogen storage diseases result in conditions ranging from difficulty exercising to cardiac and respiratory failure.

Description

Glucose is a simple sugar that functions as a critical energy source for most bodily functions. Glucose can be acquired through the diet or formed within the bodily cells. Levels of glucose in the blood are maintained in a very narrow range before and after the ingestion of food. Eating a meal supplies a high level of dietary glucose. Hormones, such as insulin, assist in the removal of glucose from the blood and into cells to be used as energy. Excess glucose is accumulated in the form of glycogen as a type of easily mobilized energy storage for use when food is not plentiful. Even while sleeping, glycogen stores are available to maintain blood glucose levels and energy for life.

The process of the formation of glycogen sheets is termed glycogenesis and is stimulated by hormones, such as insulin. The process of the breakdown of sheets of glycogen into usable glucose is termed glycogenolysis and is also under tight control. Hormones that stimulate glycogenolysis control enzymes to remove only the necessary amount of glucose from glycogen stores. With an average

daily food intake, glycogen stores are constantly being built up and broken down based on the needs of the body. Average glycogen stores serve as a short-term supply of glucose and need to be replenished daily. Glycogen serves as energy storage in every organ, but the liver and skeletal muscles are the main sites of glycogen deposition. The brain is dependent upon glucose for energy and so requires a certain level of blood glucose to be available at all times. Because the brain has only minimal glycogen stores, it is mainly dependent on glycogen from other organs, such as the liver.

Glycogen has separate functions in liver and muscle. Muscle uses glycogen as a fuel source with which to produce energy during activity. As muscle is being used, glycogen stores are being broken down into glucose, turned into cellular energy called ATP, and depleted. In the liver, glycogen is mainly used as a maintenance energy source for the entire body and is responsible for keeping blood glucose levels in a stable range. After ingestion of dietary glucose, the liver takes up many food breakdown products from the bloodstream, converts them into glucose, and stores them as glycogen. At some point after a meal, when blood glucose levels naturally fall, the liver uses its glycogen stores to replenish the blood with glucose. Organs that cannot create enough glycogen of their own are thus supplied.

Glycogen storage diseases may involve defects in glycogen breakdown or formation in muscle, liver, or both muscle and liver. Some classic features of GSDs that primarily involve muscle are muscle cramps, exercise intolerance, and easy fatigability. Some classic features of GSDs that primarily involve the liver are liver enlargement, liver function defects, and hypoglycemia. Most GSDs can have subtypes with onset at different stages of life. There are many types of GSD that involve different defects in glycogen utilization. The types of GSD that are best described are types I through VIII, each with a distinct name and profile.

Von Gierke disease

GSD type I is also known as von Gierke disease, which has two subtypes, GSDIa and GSDIb. GSDIa is caused by a defect in the catalytic subunit of the *G6PC* gene (17q21) in the enzyme Glucose-6-Phosphatase (G6P), which is involved in the release of precursor components from liver glycogen stores. GSDIb is caused by a defect in a protein transporter, Glucose-6-Phosphatase Transporter on the *SLC37A4* gene (11q23), used to transport the necessary precursor components of the pathway to the location of the enzyme. Without dietary glucose, the body is unable to access needed energy from the liver.

In times of fasting, which is essentially any time dietary glucose is not being ingested, severe hypoglycemia can result. Normal mechanisms are in effect in the body to sense a decrease in blood sugar, and they respond by increasing rates of glycogen breakdown to maintain blood glucose. Because of the defect in glycogen breakdown, this increase does not occur, and precursor molecules from the pathway accumulate. This causes liver enlargement and the protruding abdomen that is associated with the disease. In von Gierke disease, the defects in glycogenolysis occur at a point in the pathway that causes accumulation of glucose-6-phosphate. When glucose-6-phosphate accumulates, it diverts into other metabolic pathways that form lactic acid and uric acid. The lactic acid can acidify the blood and cause a dangerous condition known as acidosis. Uric acid accumulation can cause kidney stones and kidney dysfunction. There are also alterations in blood-clotting factors that cause these individuals to bleed very easily and for prolonged periods of time. These alterations can be dangerous. Frequent nosebleeds are associated with von Gierke disease as a result. Von Gierke disease Type Ib has other defects in blood immune system components that create susceptibility to some types of bacterial infections.

Pompe disease

GSD type II is also known as Pompe disease. There are three main subtypes of Pompe disease categorized as infantile, juvenile, and adult-onset. The infantile form primarily involves defects in utilization of cardiac muscle, skeletal muscle, and respiratory muscle. This form usually presents by the age of six months and is rapidly fatal, usually due to respiratory and cardiac failure. The adult form involves muscle glycogen stores other than cardiac muscle. The adult form is a progressive disease, but there are no heart defects. However, muscle weakness often results in respiratory failure. The juvenile form includes infants and children older than six months, and involves muscle weakness without cardiac defects. In general, the older a person is at the age of onset, the lesser the likelihood of cardiac involvement. Pompe disease is caused by defects in an enzyme, acid maltase (17q25.2-q25.3), involved in a side pathway of glycogenolysis that is not critical for most glycogen degradation. The main pathway for glycogen degradation is not defective in Pompe disease, so there is no hypoglycemia. The defect does cause an accumulation of glycogen that causes enlargement and dysfunction of the organs involved. In the infantile form of Pompe disease, this is the cause of heart disease, respiratory deficiency, and overall muscle weakness.

Cori disease

GSD type III is also known as Cori disease. Cori disease is caused by a defect in a debranching enzyme, Amylo-1, 6-glucosidase (mutations in the *AGL* gene [1p21]), that is responsible for breaking down the highly branched structure of glycogen in the liver, skeletal muscle, and cardiac muscle. This defect results in hypoglycemia that occurs a relatively short time after food intake. It is unknown why the defect in Cori disease may lead to liver damage and cancers that are not seen in von Gierke disease. It is known that the hypoglycemia that develops in Cori disease is directly involved and that the liver defects improve with age. Chronic hypoglycemia also contributes to skeletal and cardiac muscle damage in Cori disease not seen in von Gierke disease. The enzymatic defect in Cori disease also contributes to an increase in fat breakdown. Excessive breakdown of fatty acids leads to higher-than-normal levels of ketone acids, fat breakdown products, in the blood. A dangerous condition known as ketoacidosis may result in organ damage. Growth retardation is associated with Cori disease.

Andersen disease

GSD type IV is also known as Andersen disease, which usually causes symptoms within the first few years of life. Andersen disease is caused by a defect in a branching enzyme, glycogen branching enzyme (3p12.2), responsible for the highly branched structure of normal glycogen. In Andersen disease, glycogen has an abnormal, unbranched structure that cannot be properly broken down into glucose molecules and so accumulates. Most forms of Andersen disease involve the liver. Multiple bodily organs or systems may be affected, including the heart, gastrointestinal tract, skin, intestine, brain, blood formation, and nervous system. Andersen disease is characterized by liver enlargement, liver-induced hypertension (portal hypertension), liver cirrhosis and failure, and often death by five years of age. Some Andersen patients have a mild disease variant with later onset associated with a non-progressive form of liver disease. This subtype may have its onset even in adulthood. Some forms of Andersen disease have primarily muscle involvement that may include cardiac muscle. The abnormal glycogen in skeletal muscle results in weakness, exercise intolerance, and muscle wasting. Abnormal glycogen in cardiac muscle can lead to cardiac failure. The abnormal glycogen formed in Andersen disease can also affect the nervous system by impairing mental function.

McArdle disease

GSD type V is also known as McArdle disease. McArdle disease is caused by a defect in an enzyme, glycogen phosphorylase of muscle or myophosphorylase

(11q12-q13.2), involved in initiating glycogen breakdown, specifically in skeletal muscle. As a result, glycogen is not broken down into glucose in skeletal muscle, which causes a deficit in cellular energy (ATP). Normal energy utilization in skeletal muscle involves breaking down glycogen fuel stores into glucose and converting glucose into ATP for energy. During exercise, the amount of ATP required for performance is greatly increased. When muscle glycogen is depleted, muscle begins to use blood glucose and fat breakdown products for energy. Individuals with McArdle disease often experience a “second wind” phenomenon in energy levels during exercise because of these secondary fuel sources. However, McArdle disease still causes muscle cramps during exercise, and exercise intolerance.

Hers disease

GSD type VI is also known as Hers disease. Similar to McArdle disease, the classic form of Hers disease is caused by a partial defect in the liver glycogen phosphorylase enzyme (*PYGL* gene [14q21-q22]). This form of Hers disease involves a partial defect in liver phosphorylase, which initiates glycogen breakdown, specifically in the liver. Other forms exist that are caused by similar defects. Hers disease includes a heterogeneous group of subtypes with mild clinical consequences. Hers disease typically involves liver enlargement, muscle weakness, growth retardation, mild fasting hypoglycemia, and mildly elevated ketone levels during childhood that resolve by puberty. Most patients have only partial impairment of glycogenolysis due to the incomplete deficiencies of the enzymes involved.

Genetic profile

The GSDs are autosomal recessive diseases, which are caused by the inheritance of two defective copies of a gene. Each parent contributes one copy of the gene for the enzymes or transporters involved in GSDs. If both copies are defective, the result is disease. If only one defective copy is present, the disease does not occur but the defective gene can still be passed on to subsequent generations. If both parents carry a defective gene, then each offspring has a 1 in 4, or 25%, chance of inheriting the disease. Populations with a high frequency of healthy individuals carrying defective genes will also have higher prevalence of offspring with the disease.

Von Gierke disease GSDIa and GSDIb are caused by mutations on chromosomes 17 and 11, respectively. GSDIa is caused by deficient activity of the enzyme glucose-6-phosphatase, both negatively impacting glycogenolysis. Pompe disease is caused by mutations on chromosome 17 that result in different types of dysfunction of the enzyme glucosidase. Mutations in Pompe disease

may cause the complete absence of the enzyme, a normal amount of enzyme with reduced activity, or a reduced amount of enzyme with normal activity. The infantile subtype usually displays an absence of enzyme activity, whereas the other forms involve enzyme levels or functionality. Cori disease may involve many different mutations in chromosome 1, and any combination of defective genes may lead to the disease. There may be a generalized debrancher enzyme deficiency in Cori disease or genetic mutations in only some of the tissue-specific enzyme types.

All forms of Andersen disease result from mutations on chromosome 3 in the genes for glycogen-branching enzymes. The branched structure of glycogen is necessary for compaction and breakdown. The mutations seen in Andersen disease cause an abnormal unbranched form of glycogen. Mutations may be generalized for all types of branching enzyme or tissue-specific. McArdle disease can be caused by multiple types of mutations on chromosome 11 for the muscle-specific form of the phosphorylase enzyme. Most cases involve the functional absence of the enzyme. Hers disease is due to mutations in multiple genes on multiple chromosomes that cause defects in liver phosphorylase enzyme pathways. Some types of the Hers form are autosomal recessive, like other GSDs. Some subtypes have been reported that display X-linked recessive inheritance. In this mode of inheritance, mothers carrying defective X-linked genes can pass one copy to each offspring. However, because female offspring also receive a normal X-linked gene from the father, female offspring do not actually develop the disease. Male offspring who receive their only X chromosome from the mother can develop the disease.

Demographics

GSDs have autosomal recessive inheritance and so occur with equal frequency in both sexes. GSDs as a group have a frequency of 1 per 20,000–25,000 births internationally. Approximately 80% of all GSD cases are a combination of von Gierke, Cori, and Hers diseases, with each contributing equally. All three subtypes of Pompe disease combined are estimated to occur at a rate of 1 per 40,000 individuals in the United States, and they account for approximately 15% of GSD cases worldwide. Cori disease is prevalent among Sephardic Jews of North African descent. In this population, the frequency is approximately 1 per 5,400 individuals. Even within the same mutation type, the physical effects of Cori disease in this population are variable. Andersen disease is uncommon and is responsible for only 3% of all GSD cases. It is prevalent among Ashkenazi Jews. McArdle disease is also rare, with only a few hundred cases reported in the United States. It may be underdiagnosed

because of its mild disease course. Only a few cases of early-onset McArdle disease have been reported. Classic McArdle disease has an adolescent onset. However, cases have been reported with onset in the sixth decade of life. Hers disease is responsible for approximately 30% of GSD cases, while approximately 75% of Hers disease is the X-linked form. Hers disease is prevalent in the Menonite population, with a frequency of 0.1%. X-linked recessive forms of Hers disease are expressed primarily in affected males. Some breakthrough expression has still been reported in carrier females with mild symptoms.

Signs and symptoms

Von Gierke disease

Infants born with von Gierke disease display initial symptoms of hypoglycemia immediately following birth. These symptoms may include tremors, cyanosis (bluish tint in the skin and mucous membranes from lack of oxygen), and seizures. Some infants are born with enlarged livers and abdomens. Onset of von Gierke disease in an older infant may also include symptoms of fatigue, difficulty waking from long periods of sleep, tremor, extreme hunger, poor growth, short stature, and a protruding abdomen with thin limbs from liver enlargement. A doll-like facial appearance is often caused by fat deposits in the cheeks. Young children with von Gierke disease may additionally have fat deposits called xanthomas on the elbows and knees, frequent nosebleeds, gingivitis (inflammation of the gums), and skin boils. Symptoms of severe hypoglycemia at all ages are likely to follow any illness or circumstance that causes a decrease in food intake. In later years, children may have rickets and anemia. Enlarged kidneys may be discovered by ultrasound imaging techniques. Complications that may arise from von Gierke disease are severe hypoglycemia, liver cancer, kidney damage, fluid retention in the brain, coma, and death. In GSDIb, severe recurrent infections from immune compromise may also be a complication.

Pompe disease

Infants born with Pompe disease display initial symptoms of protruding abdomen due to liver enlargement, muscle enlargement, muscle weakness, and respiratory and feeding difficulty. Pneumonia is a complication. A heart murmur may be audible upon physical examination. Enlargement of the left ventricle of the heart may cause obstruction of blood flow and cardiac failure. The juvenile subtype of Pompe disease displays symptoms of delayed motor development, weakness, and poor muscle tone. The adult subtype has symptoms of muscle weakness, especially when performing tasks such as climbing stairs or exercising. Approximately one-third of cases involve respiratory complications.

Cori disease

Infants born with Cori disease may be healthy for the first few months of life, then present with initial symptoms of tremors, sweating, irritability, difficulty feeding, respiratory complications, seizures, coma, and sudden death. Older infants may also present with difficulty waking from sleep, poor growth, increased appetite, and dizziness. The level of hypoglycemia associated with this disease ranges from mild to severe. An enlarged liver may or may not be present. Some patients with Cori disease have improvement in the liver complications as they get older, but others develop liver cirrhosis, liver failure, and liver cancer after puberty. Approximately 85% of patients with Cori disease have significant involvement of both the liver and skeletal muscles. During childhood, complications with muscle are often minimal, but they progressively get worse with age to the point of disability. Some patients may develop an enlarged heart, but otherwise, cardiac defects are rare. Often, Cori disease causes poor growth with a short stature in children. If blood glucose levels are appropriately maintained, the attainment of normal growth is possible.

Andersen disease

Infants born with Andersen disease usually fail to thrive during the first year of life. In some cases, liver enlargement may lead to a protruding abdomen, liver cirrhosis, jaundice, hypertension, fatigue, bruising or bleeding easily, and liver failure. In other cases, the muscles may primarily be affected, causing weakness, fatigue, and muscle wasting. Muscle complications may extend to cardiac muscle and cause defects in function. If damage to the nervous system occurs in addition to muscular deficits, there may be decreased reflexes, sensory loss, and gait disturbances. Mild mental impairment may occur.

McArdle disease

McArdle disease usually has a primary symptom of exercise intolerance with muscle weakness and fatigue. The symptoms occur during strenuous or sustained exercise and usually resolve with rest. Often there is a “second wind” of energy from glucose and fat breakdown products supplied by the blood. Symptoms may range from mild fatigue to temporarily incapacitating fatigue with muscle cramping. Late-onset cases may begin showing symptoms of progressive muscle weakness at 60–70 years of age. Other cases may present symptoms in the first year of life and become severely progressive. Even in the absence of exercise, one-third of patients experience weakness. This symptom is especially common in older age. One-half of cases filter blood in the urine after intense exercise, which may be indicative of

impending kidney failure. A small percentage of McArdle patients have seizures.

Hers disease

Hers disease usually has onset between the first and fifth year of life. Classic symptoms include a protruding abdomen due to enlarged liver, delay in growth with childhood short stature, and delayed motor development. Mild hypoglycemia may also be present, but many patients develop no other symptoms. Normal growth may be eventually achieved, along with a complete resolution in liver size to normal. Muscle strength in adults is usually normal.

Diagnosis

Von Gierke disease

Von Gierke disease is diagnosed through various types of testing. Characteristically, blood tests will reveal low blood sugar and the presence of lactic acid. Tests may also be performed to assess blood glucose levels after various challenges, such as administration of hormones that normally cause glycogen breakdown into glucose. Tests are done to assess for the presence of uric acid in the blood, kidney function, and liver function. GSDIa has a normal white blood cell (immune cells) level in the blood because the immune system is unaffected in this subtype. However, in subtype GSDIb, the immune system is impaired and has lower than normal blood levels of white blood cells. Most cases also involve a defect in blood coagulation, and tests are performed to assess bleeding times in a controlled setting. Ultrasound imaging of the abdomen is performed to assess liver and kidney size. To confirm a diagnosis, a biopsy of liver tissue is used to assess the function of the glucose-6-phosphatase enzyme that presents as defective in von Gierke disease.

Pompe disease

Blood tests are performed that can assess whether muscle disease is present by assessing for various factors, such as the enzyme creatine kinase, that are normally present inside muscle cells but not in the blood. The release of high levels of these factors into the bloodstream indicates a complication. Tests for the function of the enzyme alpha-glucosidase are performed to attain a definite diagnosis. This test may be done on white blood cells, but in infants it requires an amount of blood drawn that might not be practical. Instead, a skin biopsy is usually performed to test for the enzyme. Ultrasound imaging and tests that assess the heart's response to electrical stimulation are performed to diagnose the presence or extent of cardiac muscle defects.

Cori disease

Blood tests are done to assess blood glucose and uric acid levels. Liver function studies are performed to determine the presence or extent of liver damage. Tests may also be performed to assess blood glucose levels after various challenges, such as administration of hormones that normally cause glycogen breakdown into glucose. Both blood and urine are tested for the presence of ketone bodies, products of fat breakdown that can lead to dangerously acidic blood. Ultrasound imaging can assess for heart and liver enlargement or the presence of disease. Ultrasound imaging is also used to assess for polycystic ovaries in females, a common occurrence in Cori disease that does not seem to affect fertility. A definite diagnosis involves tests that demonstrate abnormal, unbranched glycogen along with a debrancher enzyme deficiency in liver and muscle tissues.

Andersen disease

To assess for liver complications, blood tests are performed to check for the presence of enzymes that are normally present in healthy liver cells and not in significant quantities in the blood. Distinct signs of liver cirrhosis or dysfunction may also be found in the blood. Ultrasound imaging can assess for liver enlargement, liver cirrhosis, and cardiac abnormalities. Cases in which there are primarily muscle, nervous system, or cardiac defects may have no sign of liver dysfunction. Blood glucose levels are tested to assess for hypoglycemia. To confirm a diagnosis of Andersen disease, a defect in glycogen-branching enzyme activity must be demonstrated from tissue samples. Most cases can be assessed from a variety of different tissue types. A biopsy of the liver or other affected organs, such as the heart, may be taken for microscopic examination and to assess enzyme activity. In Ashkenazi Jews, deficient glycogen-branching enzyme activity is only seen in white blood cells and nerve cells. Prenatal enzyme testing can be done from amniotic samples.

McArdle disease

Blood tests in McArdle cases show elevated levels of enzymes, such as creatine kinase, that are normally present inside muscle cells but not in the blood. The release of high levels of these factors into the bloodstream indicates a complication. Exercise does not produce an increase in blood lactic acid in McArdle disease. An electromyogram (EMG) is a graphic record of a muscle contraction in response to electrical stimulation. Half of all McArdle patients have abnormalities in EMG. A muscle tissue biopsy may be assayed for muscle glycogen phosphorylase enzyme activity.

Hers disease

The extent of abnormal blood testing results are variable and usually mild in Hers disease. There may be some hypoglycemia, ketone bodies in blood and urine, elevated blood triglycerides, or enzyme levels that indicate liver complications. Ultrasound imaging may be used to assess liver enlargement. Tests may also be performed to assess blood glucose levels after various challenges, such as administration of hormones that normally cause glycogen breakdown into glucose. To confirm a diagnosis of Hers disease, a liver biopsy is taken to assess liver glycogen phosphorylase activity.

Treatment and management

Drug therapy and enzyme supplementation are not standard parts of treatment for GSDs. Treatment focuses on maintaining blood glucose levels and treating the symptoms of complications that may arise from the disease. In most cases, this may involve frequent daytime feedings, and for infants, overnight use of a specialized nasogastric feeding tube equipped with an alarm. In most GSDs, children two years of age and older can be switched to cornstarch feeding at bedtime. Raw cornstarch, but not other types of starch, can sustain blood glucose for 4–6 hours if mixed with water at room temperature. Hot water significantly reduces the time frame in which cornstarch can sustain blood glucose levels. Any illness or condition that reduces the amount of food intake requires supplemental injections of simple sugars, such as dextrose, or intravenous administration of glucose. Caregivers need to be educated in inserting feeding tubes, dietary control, and recognizing and managing hypoglycemia.

Diet is a critical component of treatment for most GSDs and must be closely monitored by highly specialized nutritionists. Von Gierke disease requires dietary avoidance of excessive carbohydrates, fat, or calories. All contact sports should be avoided because of the potential for excessive bleeding and liver damage. Iron supplementation is advised because of liver deficiencies. In GSDIb, an immune cell booster called granulocyte colony-stimulating factor (GCSF) is administered because of the depressed immune system. Dental and oral health needs to be actively maintained in GSDIb to prevent infections. Cori disease does not involve the same carbohydrate restrictions, but avoiding excessive fat intake is advised. Cori disease is also treated with a high protein diet to supplement muscle function. Cori disease does not involve sports restrictions past the personal limits of the individual's energy and blood glucose levels. Rupture of the liver from contact sports has not been reported in Cori disease. The infantile subtype of Pompe

KEY TERMS

Amniotic sample—Sample of amniotic fluid, the protective fluid surrounding a fetus in the womb.

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Boils—Painful areas of skin inflammation caused by infection of hair follicles.

Branching enzyme—Enzyme responsible for building the branched structure of glycogen stores.

Cirrhosis—A chronic degenerative disease of the liver in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

Coagulation—The solidification or change from a fluid state to a semisolid mass; blood coagulation helps to close open wounds.

Cyanosis—A bluish discoloration of the skin and mucous membranes.

Debranching enzyme—Enzyme responsible for breaking down the branched structure of glycogen stores to release glucose into the bloodstream.

Gait disturbances—Disturbances that affect a person's habitual manner of walking.

Gastrointestinal tract—The food intake and waste export system that runs from the mouth through the

esophagus, stomach, and intestines to the rectum and anus.

Gingivitis—Inflammation of the gums of the mouth, characterized by redness, swelling, and a tendency to bleed.

Glycogen—The chemical substance used by muscles to store sugars and starches for later use. It is composed of repeating units of glucose.

Glycogenesis—The metabolic process responsible for the formation of glycogen from many glucose molecules.

Glycogenolysis—The metabolic process responsible for the breakdown of glycogen to mobilize glucose.

Hypoglycemia—An abnormally low glucose (blood sugar) concentration in the blood.

Jaundice—Yellowing of the skin or eyes due to excessive bilirubin in the blood.

Ketone bodies—Fat breakdown products that can make the blood acidic when present in high levels.

Left ventricle—Lower chamber of the heart from which blood is pumped into the system.

Precursor components—Components in an enzymatic pathway that are formed by previous cellular events.

Rickets—A childhood disease caused by vitamin D deficiency, resulting in soft and malformed bones.

Xanthoma—Small yellow fat deposits that appear in the skin.

disease may not improve with dietary changes and may become fatal. A high protein diet may assist with muscle functioning in people affected with McArdle disease and with adults with Pompe disease. Supplementation with B vitamins may make muscles less prone to fatigue in McArdle disease. McArdle cases are advised to avoid sustained, strenuous, or weight-bearing exercise to prevent kidney damage. While Hers disease requires avoiding long periods of fasting, most cases do not require significant dietary intervention or exercise reduction unless there is significant liver enlargement.

Blood glucose monitoring is done with specialized home kits called glucometers, which provide an exact reading of blood glucose. A test strip is used to collect a small drop of blood obtained by pricking the finger with a small needle called a lancet. The test strip is placed in the meter, and results are available within 30–45 seconds. Testing is done on a regular basis to monitor the balance

between food intake and blood sugar levels. If hypoglycemic episodes occur, drinking fruit juice or taking a few teaspoons of sugar may bring blood glucose levels back to normal. If 15 minutes have passed and blood sugar has not returned to normal, a second dose is administered.

Specialists are frequently consulted to monitor liver complications that arise in some GSDs. Andersen disease often requires liver transplantation for effective treatment. However, some cases of Andersen disease still result in a poor outcome after liver transplant. Specialists also monitor and provide symptom-specific management of cardiac and nervous system complications that arise from GSDs. Parents of children with GSDs are given genetic counseling regarding the risk of GSD to future pregnancies. There is a 25% recurrence risk for each subsequent pregnancy in most GSDs. There is a 50% chance of male offspring having X-linked forms of Hers disease.

QUESTIONS TO ASK YOUR DOCTOR

- How is a glycogen storage disease passed to my child?
- How is a glycogen storage disease diagnosed?
- How is a glycogen storage disease treated?
- Is a glycogen storage disease a life-threatening condition?

Prognosis

The prognosis of GSD is highly varied. Overall, the long-term prognosis depends on the extent, severity, and progression of the disease. GSDs are generally multisystem diseases with many potential complications. With von Gierke disease and Cori disease, many patients receiving proper treatment do not encounter life-threatening hypoglycemia and have a reasonable lifespan. However, some patients may develop liver cirrhosis, liver cancer, or liver failure. Pompe disease is also variable in prognosis. The infantile form is usually fatal within the first year of life. Death results from cardiac and respiratory failure. The juvenile (intermediate) form progresses more slowly but is generally fatal by the second or third decade of life. Most deaths are from respiratory failure. The adult form may afford survival for several decades after onset. However, muscle weakness may interfere with normal daily activities, and death may result from respiratory failure.

Andersen disease has a very poor prognosis, with the classic infantile form causing progressive liver cirrhosis and death by five years of age in the absence of a liver transplant. Liver transplantation still does not guarantee improvement. Cases involving non-progressive liver disease do not require liver transplantation but are still at increased risk of liver cancer. Cases involving cardiac complications often lead to heart failure, despite medical intervention. Andersen disease involving nervous system and skeletal muscle complications may not be life-threatening, but it may be progressive and debilitating.

The prognosis of McArdle disease is comparatively better than many other forms of GSDs. The primary complications are muscle weakness, cramping, and fatigue, which can interfere with normal daily activities. Some patients are able to adapt exercise to take advantage of the second wind phenomenon, as long as it is not too strenuous. Prognosis remains good as long as sustained, strenuous, and weight-bearing exercises are avoided, which can lead to acute renal failure. The infantile form

of McArdle disease has a poor prognosis, with death caused by severe and rapidly progressive muscle weakness that leads to respiratory failure. The best prognosis of the GSDs described is with Hers disease. Hers disease has a mild course with risk of growth retardation, mild fasting hypoglycemia, and delayed motor development in early childhood. However, these clinical features usually normalize by the time of puberty, along with liver enlargement and muscle weakness. Adult patients usually have normal stature and motor functions. Hers disease may have an excellent prognosis even without childhood dietary management.

GM1-gangliosidosis

Definition

GM1-gangliosidosis is a lysosomal storage condition caused by a reduction in the amount of—or the absence

of—the enzyme beta-galactosidase in cells. This condition has been referred to by other names such as Norman-Landing disease, gangliosidosis-GM1 beta-galactosidase-1 deficiency, Hurler-variant, pseudo-Hurler disease, Tay-Sachs disease with visceral involvement, and *GLB1* deficiency. There are three forms of this condition, determined by the type of mutation of the associated gene and the age at which the form is diagnosed.

Description

Lysosomes are structures found inside cells that contain specific proteins and enzymes that help digest or break down many of the complex biological substances found within the cells. After the lysosomes digest these substances, the remnants are then released from the cells. The role of the lysosome is to keep the inside of a cell clean and to help the cell function normally.

One of the lysosomal enzymes, beta-galactosidase, is necessary to digest a substance called GM1-ganglioside. When there is not enough beta-galactosidase within the lysosomes, GM1-ganglioside breaks down at a slower rate or not at all. Since GM1-ganglioside is not being digested as fast as it is being produced, GM1-ganglioside accumulates within the lysosomes. When too much GM1-ganglioside accumulates, the lysosomes stop functioning effectively, thereby causing the cell not to function properly.

When enough cells in an organ or organ system stop functioning normally, the entire organ or organ system begins to experience problems. One of the first areas where GM1-ganglioside accumulates and causes problems is within the central nervous system. Other organs and systems in the body can also accumulate GM1-ganglioside; however, signs of the excessive accumulation are sometimes not immediately apparent.

There are three types of GM1-gangliosidoses; they are grouped according to the amount of beta-galactosidase detected in the individual's leukocytes (white blood cells) or skin cells, the individual's age when symptoms appear (called age of onset), and the specific symptoms that the individual exhibits. These types are labeled type I, type II, and type III.

Genetic profile

All three types of GM1-gangliosidosis are inherited in an autosomal recessive manner. Symptoms of GM1-gangliosidosis occur when the pair of genes that produce beta-galactosidase (called *GLB1*) both contain a change, causing them not to work properly. When the *GLB1* genes do not work properly, less or no beta-galactosidase is produced. Individuals with GM1-gangliosidosis inherit one of their non-working *GLB1*

genes from their mother and the other non-working *GLB1* gene from their father. These parents are called carriers of GM1-gangliosidosis. When two people are known carriers for an autosomal recessive condition, like GM1-gangliosidosis, they have a 25% chance with each pregnancy to have a child affected with the disease.

The *GLB1* gene is located on the short arm of chromosome 3, called 3p, in the region 21.33. This is written as 3p21.33. There have been over 20 mutations identified in the *GLB1* gene that can cause the gene not to work properly. The most common type of mutation detected is a missense mutation. Typically, a gene is made up of DNA that codes for specific amino acids. It is the amino acids, when combined, that make a protein. When there is a missense mutation in a gene, the DNA code for a particular amino acid has been changed, often coding for a different amino acid. Changing the amino acid often alters the protein that is made. A change in the structure or production of a protein often alters its ability to function properly.

Most individuals with GM1-gangliosidosis are compound heterozygotes. This means that an individual with GM1-gangliosidosis has one *GLB1* gene containing one mutation and his or her other *GLB1* gene has a different mutation. Researchers do not believe that there is any correlation between specific mutations in the *GLB1* gene and the severity of GM1-gangliosidosis. An exception to this is the discovery of mutations in the *GLB1* gene that instead of causing an individual to have GM1-gangliosidosis cause the individual to have another condition called Morquio syndrome type B.

Demographics

GM1-gangliosidosis is a rare condition. It is estimated that approximately 1 in 100,000–200,000 live births is affected with this condition. Type I GM1-gangliosidosis is considered to occur more often than the other two types. There has also been an increased number of individuals living in Japan, Brazil, and the Maltese Islands diagnosed with all types of GM1-gangliosidosis. However, many researchers state that this condition is not more common in individuals of certain ethnic groups, although many of the individuals with type III GM1-gangliosidosis are Japanese. Additionally, GM1-gangliosidosis occurs with equal frequency in males and females.

Signs and symptoms

The signs and symptoms of GM1-gangliosidosis largely depend on the type an individual has. As of 2014, some researches had shown these three types to be separate and distinct, while other researchers

maintained that GM1-gangliosidosis is one disorder with a spectrum of signs and symptoms.

GM1-gangliosidosis type I

Type I GM1-gangliosidosis is also called infantile GM1-gangliosidosis, or infantile type, and it is considered the most severe form of GM1-gangliosidosis. Infants with GM1-gangliosidosis type I tend to have less than 1% of the normal amount of beta-galactosidase in their cells.

Some of the symptoms seen with type I can be apparent at birth, but all infants with type I show characteristics of the condition before six months of age. All infants with type I reach a point where they fail to gain new skills and begin to regress and lose the skills they have learned.

Several of the initial symptoms seen in infants with type I are caused by the storage of GM1-ganglioside in the cells of the infant's central nervous system. One sign of a problem with the central nervous system seen in some infants with type I is their inability to eat much food or formula because of a poor appetite and/or difficulties with sucking on a bottle or nipple. As a result, they tend to gain very little weight. Another sign of GM1-ganglioside storage in the central nervous system is muscle problems. Most of these infants have low muscle tone, called hypotonia. These babies appear "floppy" or loose. As the disease progresses, the infants present with other central nervous system problems, such as an exaggerated reaction to sound and atrophy of the optic nerves. Their bodies also become rigid and stiff, and they develop tight joints (joint contractures) and experience seizures. Infants with type I can also develop brain atrophy and/or areas of decreased amount of white matter in the brain.

In GM1-gangliosidosis type I, GM1-ganglioside is also stored in the skeleton, causing visible changes on radiographs. Some of the more common bone changes are differences in the vertebrae that cause spine curvature, a thicker skull, wider bones and hands, and wide, short fingers. Also, the growth of the bones tends to slow down or stop, causing infants with GM1-gangliosidosis type I to appear smaller than expected for their age.

Additionally, infants with type I usually develop certain characteristic facial features. The facial features typically seen in infants with type I include frontal bossing, ears that are set lower on the head than normal, thicker skin, hair on the forehead and neck, an elongated space between the nose and mouth, and an enlarged tongue. Children with these facial changes are often described as appearing coarse. Coarse facial features can also be seen in infants and children who have other types of storage disorders.

Other characteristics of GM1-gangliosidosis type I include an enlarged spleen and liver (called hepatosplenomegaly), cardiomyopathy (which has only been

described in Caucasian patients), and an enlargement of the cells in the bone marrow. Additionally, infants with type I have cherry-red spots in the macula of their retinas, and several develop corneal clouding.

GM1-gangliosidosis type II

GM1-gangliosidosis type II is also referred to as the juvenile or intermediate type. In children with type II, the amount of beta-galactosidase in the cells is approximately 1%–5% of normal.

Type II GM1-gangliosidosis is characterized by a slower progression of symptoms and a shortened life expectancy of early adulthood. Signs of type II often appear late in infancy or in early childhood around 18 months to five years of age. Although each individual with type II may present differently, several children with type II have been reported to have difficulty walking and to have developed seizures and/or developmental regression. The bone changes seen in type I may or may not occur in children with type II. Furthermore, children with type II do not have macular cherry-red spots, enlarged spleen or liver, or the facial changes associated with type I.

GM1-gangliosidosis type III

Individuals with GM1-gangliosidosis type III are labeled as having the adult or chronic type of this condition. Individuals with type III tend to have approximately 10% of the normal amount of beta-galactosidase in their cells. The age when symptoms begin to appear in individuals with type III is extremely variable. There have been reports of individuals with type III exhibiting symptoms as early as 3 years of age to as late as 30 years old. The symptoms slowly worsen over many years.

Individuals with GM1-gangliosidosis type III tend to experience some symptoms related to the storage of GM1-ganglioside in their central nervous system; however, these symptoms are not as severe as those seen in infants with type I. The signs of GM1-ganglioside storage can be different in each person affected with GM1-gangliosidosis type III, but many individuals with type III have been reported to have signs of dystonia. Other neurological symptoms in type III can include difficulty or unusual methods of walking (ataxia), mild mental delays, and slurred speech. Often the ataxia and slurred speech are some of the first symptoms to appear.

Individuals with type III also have GM1-ganglioside storage in bone cells, but bone changes are considered milder than those seen in type I. Often the vertebrae of individuals with type III tend to have a flattened appearance and/or the presence of other mild vertebral changes. On CT or MRI examinations, mild brain atrophy with

KEY TERMS

Amino acids—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (8 are essential amino acids that the body cannot make and must therefore obtain from food).

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Atrophy—Wasting away of normal tissue or an organ due to degeneration of the cells.

Basal ganglia—A section of the brain responsible for smooth muscular movement.

Cardiomyopathy—A thickening of the heart muscle.

Cytoplasm—The substance within a cell, including the organelles and the fluid surrounding the nucleus.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Dystonia—Painful involuntary muscle cramps or spasms.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Frontal bossing—A term used to describe a rounded forehead with a receding hairline.

Gray matter—Areas of the brain and spinal cord that are made up mostly of unmyelinated nerves.

Lysosome—A membrane-enclosed compartment in cells that contains many hydrolytic enzymes; where large molecules and cellular components are broken down.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and that can be transmitted to offspring.

Myelin—A fatty sheath surrounding nerves in the peripheral nervous system that helps them conduct impulses more quickly.

Organelles—Small subcellular structures that carry out different functions necessary for cellular survival and proper cellular functioning.

White matter—A substance found in the brain and nervous system that protects nerves and allows messages to be sent to and from the brain to the various parts of the body.

signs of storage in the basal ganglia can be present in some individuals with type III. Also, some individuals with type III have experienced corneal clouding. However, the macular cherry-red spots, facial changes, and differences in the bones are not seen in individuals with GM1-gangliosidosis type III.

Diagnosis

The diagnosis of GM1-gangliosidosis in an individual can be made by measuring the amount of beta-galactosidase in either skin cells or in leukocytes. Additionally, prenatal testing to determine whether a fetus is affected with GM1-gangliosidosis prior to its delivery can be accomplished by measuring the amount of beta-galactosidase on cultured cells from an amniocentesis or chorionic villus sampling (CVS). Amniocentesis is a procedure used to remove some of the fluid, which contains fetal cells, from around the fetus. CVS is used to obtain cells from the placenta. With both of these procedures, the cells collected are stimulated to multiply so that there are enough cells to perform certain analyses, in this case measuring the amount of beta-galactosidase. Both of these procedures have their own risks, benefits, and limitations.

X-rays can detect bone changes and organ enlargement. However, in early stages of the condition, bone differences may not have developed or the organs may not yet be enlarged. A CT scan and/or MRI can identify brain changes, such as cerebral atrophy or a loss of myelin in the white matter of the brain. An eye examination can detect any macular cherry-red spots or other changes.

Analysis of the amount of beta-galactosidase in an individual's cells cannot be used to determine whether the person is a carrier of GM1-gangliosidosis. This is because the range for the amount of beta-galactosidase seen in carriers of this condition overlaps with the range of the amount of beta-galactosidase seen in individuals who are not carriers.

As of 2021, molecular genetic testing of the *GLB1* gene is available from the Centogene AG laboratory in Germany. The test can be performed on amniotic fluid, fetal blood, bone marrow, a buccal swab, fresh or frozen tissue, and isolated DNA.

Treatment and management

There is no cure for GM1-gangliosidosis. Most of the treatments revolve around trying to alleviate some of the

QUESTIONS TO ASK YOUR DOCTOR

- What type of gangliosidosis does my child have, and what is his or her life expectancy?
- What will daily life be like while taking care of a child with gangliosidosis?
- Are there at-home care services we could utilize for physical and occupational therapy, if needed?
- How should my child be monitored for changes in other organs or organ systems?
- How far into my next pregnancy should I be tested for carrying a child with this disorder?
- Are there any organizations for emotional and/or financial support established to help us take care of a child with this syndrome?

symptoms, such as helping infants with type I to eat, and providing devices that can help with problems walking in individuals with type III. Physical therapy, occupational therapy, and early intervention for education and social outcomes are also important for the daily and overall life activities of an individual. Management often includes routine monitoring of growth and neurological function as well as nutritional assessment, cardiac examination, and assessment of the stability of the spine. Additionally, there is ongoing research into gene therapy for GM1-gangliosidosis to infuse genes that produce beta-galactosidase into the body.

Prognosis

In type I GM1-gangliosidosis, the child dies within a few years after the symptoms begin, typically by age two. In type II GM1-gangliosidosis, the prognosis is variable. Some individuals have died during childhood or early adulthood, and others have lived many years after symptoms began. In type III GM1-gangliosidosis, no decrease in lifespan has been reported.

Greig cephalopolysyndactyly

Definition

Greig cephalopolysyndactyly (GCPS) is a very rare autosomal dominant disorder. The syndrome is characterized by physical abnormalities of the head, face, fingers, and toes. Distinct features include extra fingers and/or toes; a large and unusual shape of the skull; a high, prominent forehead; and widely spaced eyes. The range and severity of symptoms may vary greatly between individuals. Some individuals with Greig cephalopolysyndactyly require medical or surgical intervention to manage these problems. The syndrome is familial and in most cases is transmitted as an autosomal dominant trait.

Description

The disorder is named for D. M. Greig (pronounced Gregg), a Scottish physician, who first described the features of this syndrome in 1928. He saw a mother and her daughter who had a peculiar shape of the skull (cephalus) and polysyndactyly of the hands and feet. Polysyndactyly means that the patient has both extra digits (toes, fingers) as well as webbing (syndactyly) between the digits. Dr. Greig described them as having a high forehead and widely spaced eyes. Thus, the syndrome was termed Greig cephalopolysyndactyly.

Genetic profile

Greig cephalopolysyndactyly can be found in several generations of a family. It is an autosomal dominant disorder and can be inherited and passed on by men as well as women. Almost all genes come in pairs. Cells work best when both copies of the gene pairs are intact and do not have mutations. One copy of each pair of genes is inherited from the father, and the other copy of each pair of genes is inherited from the mother. Therefore, if a parent carries a gene mutation for GCPS, each of his/her children has a 50% chance of inheriting the gene mutation. Each child also has a 50% chance of inheriting the working copy of the gene, in which case they would not have GCPS.

The search to find the causative gene took a number of years. The first clue came in 1989, when an 11-month-old infant was found to have a deletion of genetic material on chromosome 7. The infant had a large head and polysyndactyly of the hands and feet. Other reports soon followed, with small deletions and translocations of chromosome 7. Then, in 1991, investigators began to study a gene called *GLI3* as the candidate gene. This gene was found in the region of chromosome 7p13, which was missing in these individuals. The *GLI3* gene was also suspect because of previous studies done in mice.

The mouse gene *GLI3* normally functions in the design of the skeleton and limbs in the embryo. The *GLI3* gene also works in the developing brain. Mice lacking both copies of the gene die before birth. Many have severe birth defects of the brain, skeleton, and central nervous system. However, mice with just one non-working copy of the *GLI3* gene do not die. They have minor birth defects, most notably extra digits, often of the hind feet. The mice also have a duplicated bone in their front feet, and an enlarged bone in the front portion of the skull. This combination of birth defects is unusual, but common to both Xt mice and individuals with Greig cephalopolysyndactyly.

With this in mind, the *GLI3* gene was scanned for alterations (mutations) in individuals with GCPS. Of interest, both small and large mutations were found throughout the coding regions of the gene. As none of these mutations were found in unaffected individuals, this proved that the *GLI3* gene was the cause of the condition.

In addition to GSPC, Pallister-Hall syndrome and post-axial polydactyly type A (PAP-A), two other disorders of human development, are caused by alterations in the *GLI3* gene. The common feature of each disorder is polydactyly of the hands and feet. However, individuals with Pallister-Hall syndrome have additional growth problems and severe intellectual disability. Extra fingers and

toes are the primary feature of PAP-A, and thus, the most mild in expression of the three conditions.

Scientists have used animal models and the fruit fly *Drosophila* to study the function of the *GLI3* gene. The normal function of the GLI3 protein is to bind to the DNA helix at specific places. By doing so, it helps to regulate which genes are activated or “turned on.” Many of the mutations identified so far seem to interfere with the protein binding function. In effect, other genes that would normally be activated during development of the embryo may in fact not be turned on.

It is known that the limbs (arms, legs, fingers, toes) develop between the fourth and eighth week of pregnancy. The limb defects seen in GCPS must occur during this crucial period of development.

Demographics

Greig cephalopolysyndactyly affects both males and females equally. It most likely occurs in every race and ethnic group. In all, about 200 individuals have been described worldwide, but it is possible that the disorder is underdiagnosed because some affected persons may have only mild symptoms. Therefore, it is a rare condition.

Signs and symptoms

Most individuals with Greig cephalopolysyndactyly have a large head circumference (the distance as measured around the cranium). The forehead is high and wide, and slightly rounded in front (frontal bossing). This is due to the cranial sutures closing later than normal, causing the bones of the forehead to remain apart. The widening of the forehead appears to dip down into the space between the eyes, setting the eyes farther apart than normal. The bridge of the nose is broad and flat. This adds to the impression of distance between the eyes. Many times, the rest of the face will also look broad, almost box-like. The chin is small in comparison. The mouth is wide, and the corners of the mouth may be turned downward. The ears are usually normal. Individuals with GCPS can have a short neck, making it look as if the head rests on the shoulders. Intelligence is usually normal, although a few individuals have had mild learning disabilities.

The hands are quite distinctive in appearance. Most individuals with GCPS have extra fingers on each hand. The extra finger is rarely on the thumb side (pre-axial polydactyly). It is most often on the pinky finger side (post-axial polydactyly). Some individuals have an extra finger on each side of the hand, and thus, the possibility of 14 fingers. However, the extra finger may or may not include bone, and could just be a skin tag. The thumbs are frequently quite wide in appearance. Sometimes the bones of the thumb are

Chromosome deletion—A missing sequence of DNA or part of a chromosome.

Chromosome translocation—The exchange of genetic material between chromosomes, which can lead to extra or missing genetic material.

Hypospadias—An abnormality of the penis in which the urethral opening is located on the underside of the penis rather than at its tip.

Polysyndactyly—Having both extra digits (toes, fingers) as well as webbing (syndactyly) between the digits.

Post-axial polydactyly—An extra finger or toe on the outside of the hand or foot.

Pre-axial polydactyly—An extra finger or toe on the inside of the hand or foot.

duplicated or split at the tip. There may also be duplication or fusion in some of the bones that make up the hand, which can be seen on x-ray. Their hands are still quite functional, although surgery may be necessary.

Many of these patients have extra toes. What is unusual is that the extra toe is most often on the great toe side, opposite to what is found in the hands. The toes may also be short. Syndactyly (extensive webbing of the skin) is a constant finding in these patients. The webbing is usually between the toes, but may involve the hands. The webbing can vary from being mild, to complete joining of the digits, with skin up to the nail. Sometimes, just a few of the digits are fused together; in others, all of the toes are webbed. The webbing may be present alone without extra toes, although this is uncommon. The syndactyly may also occur on just one foot, and can be quite variable. Foot mobility and walking is usually not a problem.

There are other occasional problems seen in GCPS. These include craniosynostosis (premature fusion of the skull bones), mild intellectual disability, hernia of the abdominal (stomach) muscles, and lesser birth defects of the urinary tract system, such as hypospadias in males.

Diagnosis

Each individual with Greig cephalopolysyndactyly is affected somewhat differently. The features are usually

quite variable, even within the same family. The facial features can be mild with most individuals only having a high and broad forehead.

Polysyndactyly of the hands and feet remains the most distinctive feature of the syndrome. With the use of x-rays, changes in the bones of the hands and feet can be seen. The diagnosis of GCPS is suspected when the physician identifies the extra digits on the outside of the hands and on the inside of the foot, along with the broad forehead. This is usually seen at birth.

The availability of direct gene testing allows for a definitive diagnosis for these patients. Using a blood sample, a direct gene test looking for alterations (mutations) in the *GLI3* gene can be done. An identifiable gene mutation would confirm the diagnosis in sporadic (non-inherited) patients as well.

Treatment and management

Very often, the physical characteristics of the face do not require surgical treatment. Sometimes, the facial appearance even improves as the child grows. However, if the cranial sutures in the forehead close either very early or very late, there may be fairly severe disfigurement to the face. This would require surgery from a specialized craniofacial medical team. Craniofacial surgery rearranges or reconstructs the bones of the face to correct the abnormal fusion of the cranial bones.

Some degree of surgery is needed for the polydactyly of the hands and feet. The extra digits that are just skin tags (no bone within) are tied off at the base and allowed to self-amputate. This is usually done at birth. For those digits that include bone, most surgeons would save the digit that would have the best use. The other digit (or digits) would then be surgically removed, usually around one year of age. Surgery is often done to release the webbing of the fingers and toes, and can be quite extensive.

Prognosis

Most individuals with Greig cephalopolysyndactyly appear to have a normal life span.

Griscelli syndrome

Definition

Griscelli syndrome is a rare, sometimes fatal disorder that includes symptoms of partial albinism, neurological impairment, and immunodeficiency. There are three types of Griscelli syndrome, characterized by varying degrees of albinism; a partial lack of melanin, the pigment that gives color to the eyes, hair, and skin; immune system abnormalities; and intellectual and developmental delay.

Description

There are three types of Griscelli syndrome. They are diagnosed based on their symptoms and the genetic mutations that cause them. All three types involve partial albinism—hypopigmented or unusually pale skin and light silver to gray hair even in infancy.

The three types of Griscelli syndrome are the following:

- Griscelli syndrome type 1 (GST1): This type is characterized by partial albinism and neurological impairment caused by abnormalities of the brain. Individuals with GST1 experience developmental and

KEY TERMS

Melanin—A broad term for a group of pigments normally produced by the body that give color to the skin and hair.

Melanocytes—Cells that can produce melanin.

Melanosomes—Granules of pigment within melanocytes that synthesize melanin.

intellectual delays, seizures, hypotonia (muscle weakness), and eye anomalies that affect vision.

- Griscelli syndrome type 2 (GST2): This type of Griscelli syndrome does not involve neurological impairment. It is characterized by hypopigmentation of the skin and hair and immune system disorders. Individuals with GST2 suffer from frequent infections and an immune system disorder called hemophagocytic lymphohistiocytosis (HLH). HLH is a serious, sometimes life threatening condition in which the immune system produces abnormal white blood cells—specifically T cells and NK cells. Under normal circumstances, these cells destroy infected cells and protect the body; however, in those with HLH, these cells become over active and begin to attack healthy tissues and organs throughout the body, including the brain, liver, bone marrow, and others.
- Griscelli syndrome type 3 (GST3): This type of Griscelli syndrome is a less severe form of the syndrome in which the only symptoms are unusually light skin and hair color.

Genetic profile

Griscelli syndrome is caused by mutations in three genes: *MYO5A*, *RAB27A*, and *MLPH*. These genes carry the information necessary to produce proteins found in cells called melanocytes. These proteins work within cells to transport structures called melanosomes, which produce melanin, the pigment that gives eyes, skin, and hair their color. The melanosomes are created near the cell's center and must travel to the cell membrane and move into other types of cells so that normal

pigmentation can occur. If the *MYO5A*, *RAB27A*, and *MLPH* genes are mutated, the melanosomes cannot travel within the cell and begin to form clumps. These clumps prevent melanosomes from traveling and prevent melanin from being delivered to other cells to spread pigmentation. These clumps, visible in the shafts of hair when examined under a microscope, are a key feature of Griscelli syndrome.

The three genetic mutations each cause one type of Griscelli syndrome: GST1 is caused by mutations in the *MYO5A* gene on chromosome 15, GST2 is caused by mutations in the *RAB27A* gene on chromosome 15, and GST3 is caused by mutations in the *MLPH* gene on chromosome 2. All three mutations are inherited in an autosomal recessive pattern, which means both copies of the gene in each cell must have mutations. The parents of an individual with an autosomal recessive condition each carry one copy of the mutated gene, but they typically do not show signs and symptoms of the condition or syndrome.

Demographics

Both males and females are born with Griscelli syndrome. In general, Griscelli syndrome is an extremely rare condition. Of the three types, GST2 is the most common. There are fewer than ten known cases of Griscelli syndrome in the United States, and most known cases have been reported in Mediterranean populations.

Signs and symptoms

Griscelli syndrome causes pigmentary dilution of the skin and hair, and clumps of pigment in hair shafts. Griscelli syndrome also causes an accumulation of melanosomes in melanocytes.

People with Griscelli syndrome may have frequent infections in which pus is present, fever, an abnormal

decrease in the number of white blood cells, and a reduction in the number of platelets in the blood.

Diagnosis

Griscelli syndrome is generally diagnosed based on the signs and symptoms, or by microscopically examining the hair shaft. Genetic testing may be done to identify mutations in the *MYO5A*, *RAB27A*, and *MLPH* genes.

Treatment and management

Treatment options for individuals with Griscelli syndrome are limited and will depend on which type of Griscelli syndrome the patient has and how severe the symptoms.

Treatment for GST1 involves educational intervention for intellectual and developmental delays, neurological care for associated seizure disorders, and ophthalmological care for the associated eye and vision anomalies.

Treatment for GST2 is especially important because of the significant risks of repeated infections and the life-threatening risks associated with HLH. In patients with HLH, the main treatment options are stem cell transplantation and bone marrow transplantation. Both stem cell and bone marrow transplantation involve injecting the patient with stem cells and/or bone marrow from a donor who has been carefully matched to his or her blood type and human leukocyte antigen (HLA) type. HLA helps the body identify blood that belongs and other substances that must be destroyed such as infections. Siblings generally have similar HLA and often make the most compatible donors.

Generally, no treatment is required for GST3, since there are no neurological or immunological symptoms associated with this type.

Prognosis

The prognosis for individuals with Griscelli syndrome varies depending on which type they have. Those with GST1 will experience lifelong neurological impairment. Prognosis for those with GST2 is poor without bone marrow/stem cell transplantation; individuals with GST3 generally have a normal life expectancy.

Haim-Munk syndrome

Definition

Haim-Munk syndrome is an extremely rare genetic disorder similar to Papillon-Lefèvre syndrome. Features include callous patches of skin on the palms of the hands and the soles of the feet, long pointy fingers, and degeneration of the tissues that surround and support the teeth.

Description

Haim-Munk syndrome is characterized by red, scaly thick patches of skin on the palms of the hands and soles of the feet (palmoplantar hyperkeratosis) that are apparent at birth, along with frequent pus-producing (pyogenic) skin infections, overgrowth of the fingernails and toenails (onychogryphosis), and degeneration of the gums and bone surrounding the teeth (periodontitis) beginning in childhood. The severe and ongoing periodontitis usually causes the baby teeth to fall out prematurely and often results in the loss of the permanent adult teeth as well.

In 1965, researchers Haim and Munk reported findings similar to Papillon-Lefèvre syndrome in four siblings from an inbred Jewish family that originated from Cochin, India, on the Malabar Coast, and later migrated to Israel. Features that are present in both Papillon-Lefèvre syndrome and Haim-Munk syndrome include skin abnormalities and severe periodontitis. These disorders are considered alternate forms of the same genetic mutation. There are a number of additional features reported in Haim-Munk syndrome that include long, thin, pointed fingers (arachnodactyly), bone loss in the fingers or toes (acroosteolysis), abnormal changes of the nails, and a claw-like deformity of the hands.

Haim-Munk syndrome is also known as Cochin Jewish disorder or congenital keratosis palmoplantaris.

Genetic profile

Haim-Munk syndrome is a homozygous expression of an autosomal recessive trait. Among palmoplantar

keratoderma disorders, only Papillon-Lefèvre syndrome and Haim-Munk syndrome are associated with the premature loss of teeth. It is suspected that Haim-Munk syndrome could be genetically different from common forms of palmoplantar keratoderma that are linked to the cyto-keratin gene families.

Preliminary findings suggest that DNA markers other than keratin genes are responsible for the Haim-Munk syndrome. In 1997, genotype data in affected individuals found that the gene mutations in Haim-Munk syndrome were not due to a gene defect in either type I or type II keratin gene clusters on chromosomes 12 and 17, markers common to other palmoplantar keratoderma conditions.

Because Papillon-Lefèvre syndrome and Haim-Munk syndrome present different symptoms than palmoplantar keratoderma disorders, both genetic syndromes are thought to be related to specific bacterial infections in those with palmoplantar keratoderma.

The cause of Papillon-Lefèvre syndrome is a mutation in the cathepsin C gene resulting in periodontal disease and palmoplantar keratosis. Haim-Munk syndrome is thought to be a variant clinical expression of Papillon-Lefèvre syndrome that is caused by defects in the cathepsin C gene as well.

A study in 2000 reported a mutation of cathepsin C (exon 6, 2127A→G) that changes a highly conserved amino acid in the cathepsin C peptide. This suggests that Haim-Munk syndrome and Papillon-Lefèvre syndrome are alternate forms of defects in the cathepsin C gene. The study also notes that the basis for the difference in clinical expression (symptoms) of these two syndromes caused by the mutated cathepsin C gene is not known.

Demographics

The estimated occurrence of Papillon-Lefèvre syndrome, of which Haim-Munk is an extremely rare variant, is considered one to two persons per million. There appears to be no variance by gender. While Papillon-

KEY TERMS

Acroosteolysis—Loss of bone tissue at the ends of the fingers and/or toes.

Arachnodactyly—A condition characterized by abnormally long and slender fingers and toes.

Atrophy—Wasting-away of normal tissue or an organ due to degeneration of the cells.

Onychogryphosis—Overgrowth of the fingernails and toenails.

Palmoplantar keratoderma—Group of mostly hereditary disorders characterized by thickening of the corneous layer of skin (hyperkeratosis) on the palms and soles as a result of excessive keratin formation (protein in the skin, hair, and nails).

Palmoplantar keratosis—A raised thickening of the outer horny layer of the skin on the palms of the hands and the soles of the feet.

Periodontitis—Inflammatory reaction of the tissues surrounding and supporting the teeth that can progress to bone destruction, abscess formation, and eventual tooth loss.

Pes planus—Flat feet.

Pyogenic—Pus-forming.

Lefèvre syndrome cases have been identified throughout the world. Haim-Munk syndrome has only been described among descendants of an inbred Jewish family originally from Cochin, India, who migrated to Israel.

Signs and symptoms

The two major manifestations of Haim-Munk syndrome are dermatological abnormalities and juvenile periodontitis.

Individuals identified with Haim-Munk syndrome show more severe skin abnormalities than groups with Papillon-Lefèvre syndrome. Extensive palmoplantar hyperkeratosis typically begins within the first two to three years of life. At birth, the palms and soles are bright red in color and then progress to a callused and scaly appearance. As the patient gets older, the disease often involves thick, scaly patches on the entire front and back area of the hands and feet, as well as the elbows and knees.

A typical pattern of periodontitis with Haim-Munk syndrome is as follows: Initially, the deciduous (baby) teeth appear at the normal time, but the gums proceed to swell and bleed. Usually, all the deciduous teeth fall out

by age four; the mouth then heals and the secondary teeth begin to appear. Severe gingival inflammation develops, and the majority, or all, of the permanent teeth often fall out by age 15.

Individuals with Haim-Munk syndrome may also have some of the following signs and symptoms:

- wasting (atrophy) or thickening of the nails
- a deformity of the fingers called arachnodactyly—abnormally long, thin, tapered fingers and toes
- lack of normal blood flow to the extremities that results in numbness and tingling in the fingers and/or toes; it also can cause loss of bone tissue at the ends of the fingers and/or toes (acroosteolysis)
- a curve of the bones in the hands causing claw-like features
- flat feet (pes planus)
- recurrent pus-forming (pyogenic) skin infections

Diagnosis

There are no published diagnostic criteria for Haim-Munk syndrome. Researchers use clinical examination of inbred Jewish Cochin descendants to confirm the presence of Haim-Munk. Diagnosis of Papillon-Lefèvre syndrome is confirmed by red, thick, callused skin on the palms and soles at birth and dental problems that are usually present by age five.

Affected individuals are diagnosed with Haim-Munk syndrome when all of the following features are present:

- palmoplantar keratoderma
- thick, rough, and scaly patches of skin on the forearms and legs
- severe early-onset periodontitis
- arachnodactyly
- abnormal changes of the nails

Radiology is used to view the thin and tapering bone deformities in the fingers and dental problems associated with Haim-Munk syndrome.

Genetic testing can confirm the mutation of the cathepsin C gene. Genotyping for polymorphic DNA markers (D11S1887, D11S1367, and D11S1780) is used to identify the presence of the cathepsin C gene mutations associated with Haim-Munk syndrome.

Treatment and management

Treatments include extraction of the teeth and use of dental prosthesis, or dentures. Medications are also used to treat skin lesions associated with this disorder.

QUESTIONS TO ASK YOUR DOCTOR

- What is the prevalence of Haim-Munk syndrome in the general population and in any specialized population at risk for the disorder?
- What are the first symptoms of Haim-Munk syndrome to occur in a young child?
- What forms of treatment are available for controlling or curing the symptoms of Haim-Munk syndrome?
- Is there any reason for parents outside of the special group at risk for Haim-Munk syndrome to be concerned about the disease?

Prognosis

A normal lifespan has been reported for individuals with Haim-Munk syndrome. Loss of the baby teeth may occur by age six and loss of the permanent teeth by age 15; however, general health is not impaired and dentures are well tolerated.

Hair loss syndromes

Definition

Hair loss syndromes are a varied group of disorders and conditions characterized by the gradual or sudden loss of large amounts of hair—most often from the scalp, but sometimes from other areas of the body. Hair loss (or baldness) is sometimes referred to as alopecia. Madarosis is the medical term for the loss of eyelashes (ciliary madarosis) or eyebrows (superciliary madarosis).

Genetic factors are the most common cause of alopecia. Studies have shown that 80% of hair loss cases are indeed due to genetic factors. Although hair loss, unlike some genetic disorders, is not a life threatening or disabling condition, it often has painful psychological consequences. Good grooming and an attractive appearance are important factors in the contemporary job market as well as interpersonal relationships, and a full head of hair is considered a positive feature. Historically, men have tended to put less weight on their external appearance than women have, but this pattern has changed in the last two decades. Present evidence indicates that men are now as vulnerable to pressures to "look good" as women are and that hair loss is a frequent focus of men's concerns about their looks.

Description

Hair loss syndromes can be divided into two major categories: those caused by some type of inflammation, and those caused by genetic factors, aging, or medication side effects. The noninflammatory syndromes are subdivided into two groups according to the pattern of hair loss. The inflammatory syndromes are also subdivided into two groups according to the presence or absence of tissue destruction.

Noninflammatory patterned hair loss

ANDROGENETIC ALOPECIA. Androgenetic alopecia is the most common hair loss syndrome, accounting for about 95% of cases of hair loss. It is also referred to as androgen-dependent or genetic hair loss. In order to understand this form of alopecia, it is useful to begin with

some basic facts about the structure and growth cycle of human hair. Hair is composed primarily of keratin, a tough protein that is also found in the fingernails, toenails, and the outermost layer of skin. Each individual hair consists of a hair follicle, which is a small sac that produces the hair shaft, and the hair shaft itself. The average adult scalp contains about 100,000 hair follicles, the number depending on the natural color of the hair. Brunettes have the highest number of scalp follicles (about 155,000), followed by blondes (140,000) and redheads (85,000). The average adult loses between 70 and 100 scalp hairs per day from ordinary combing, brushing, or shampooing. A loss of more than 150 hairs per day is abnormal.

Human hair differs from the hair of other animals in that its growth cycle is not synchronized; an examination of a group of scalp hairs from the same part of the scalp will show that they are in different phases of growth. There are three phases in the human hair growth cycle. Hairs in the anagen, or growth, stage remain in the follicle during an average period of two to eight years, and grow between a quarter-inch and a half-inch per month. About 90% of scalp hairs are in the anagen phase at any one time. At the end of the anagen phase, the hair enters a

brief catagen phase lasting between two and four weeks. During this phase the follicle begins to break down. The catagen phase is followed by a telogen, or resting, phase that lasts between two and four months. Hairs in the telogen phase are shed when the growth phase of the next cycle begins and the new hair shaft pushes out the old hair. About 10% of the hairs on the scalp are normally in the telogen phase. These hairs will regrow about six months after they have been shed.

In androgenetic baldness, the hair growth cycle is affected by the rise in the level of androgens (male sex hormones) in the body that occurs at puberty. Women as well as men produce androgens, although in much smaller amounts. The amount of these hormones does not need to be abnormally high for androgenetic hair loss to occur. Males who have a normal level of androgens and a gene for baldness will develop male pattern hair loss, or MPHL. There are two androgens that contribute to MPHL, dihydrotestosterone (DHT) and testosterone.

Testosterone is converted to DHT by an enzyme called 5-alpha-reductase. In men with genes for baldness, the hair follicles in the scalp remove testosterone from circulation and convert it to DHT. The action of DHT over time shortens the duration of the anagen phase of the hair growth cycle and decreases the proportion of the hairs in the anagen phase. As the anagen phase decreases, the hairs produced are shorter in length and thinner in diameter. As a larger percentage of the hairs are in the resting or telogen phase, more are lost during normal grooming. This process of the shortening and thinning of each hair shaft is called miniaturization. Miniaturization is accompanied by the loss of hair pigment production, so the miniaturized hairs are also lighter in color. The light-colored fine hairs that are left at the end of the miniaturization process are called vellus hairs.

In MPHL, hair loss tends to occur in certain areas rather than being distributed evenly over the head. One common pattern is recession of the hair at the temples, with the man's hairline moving backward over time in an "M" pattern. The hair at the crown of the head also begins to thin, and may meet the receding hairline so that the remaining hair forms the rough outline of a horseshoe.

In female pattern hair loss, or FPHL, there is an overall thinning of the hair as well as more pronounced hair loss in certain areas of the scalp, usually the crown. Women with FPHL may find that their hairlines recede a little, but rarely to the same extent as happens in men. Androgens play the same role in hair loss in women that they do in men, since the adrenal glands and ovaries secrete small amounts of androgens.

There are other important differences between FPHL and MPHL:

- FPHL generally appears at later ages—in the woman's late 20s or early 30s—whereas MPHL can affect boys as young as 15.
- FPHL is frequently associated with hormonal changes in women, such as those that occur after childbirth, with the use of birth control pills, or after menopause.
- Women very rarely experience complete loss of hair from a specific area of their scalp due to FPHL. The process of miniaturization in FPHL affects the hair follicles at random, so some hairs are unaffected. These normal, thick hairs are interspersed among thinner, miniaturized hairs.

TRACTION ALOPECIA. Traction alopecia is a non-inflammatory patterned hair loss syndrome in which the pattern of loss is related to pulling or friction on specific areas of the scalp. It is usually caused either by hair styles in which the hair is pulled into tight braids or held too tightly by rubber bands or by frequent use of electronic headsets for long periods of time. The tension or rubbing damages the hair shafts and hinders the growth of new hair. In some cases the use of tight hair rollers at night or frequent use of blow dryers on high settings contributes to hair loss from traction alopecia.

TRICHOTILLOMANIA. Trichotillomania is a psychiatric disorder that results in patterned hair loss. It is characterized by recurrent episodes of pulling or tugging at the hair in order to relieve stress or tension. The most commonly affected areas are the scalp, the eyebrows, and the eyelashes, although some patients with the disorder pull at hair elsewhere on the body. Trichotillomania can usually be differentiated from other hair loss syndromes by laboratory study of a hair sample.

Noninflammatory diffuse hair loss

TELOGEN EFFLUVIUM. Telogen effluvium is a common cause of diffuse hair loss, which means that hairs are shed from all parts of the scalp, not just certain patterned areas. “Effluvium” is a Latin word that means “outflow” and refers to the large amounts of hair that may be lost. Persons affected by telogen effluvium may lose as much as 30%–40% of their hair in a short period of time.

Telogen effluvium results from an abnormal alteration of the hair growth cycle in which large numbers of hairs in the anagen phase suddenly switch into the telogen phase. Within six weeks to four months after this switch, these hairs begin to shed.

There are a number of possible causes for telogen effluvium, including the following:

- major surgery
- pregnancy and childbirth

- crash dieting
- nutritional deficiencies, including iron deficiency
- malabsorption syndrome
- infectious diseases accompanied by high fever, such as scarlet fever, early syphilis, or typhoid
- hypothyroidism medications

A number of medications are known to cause telogen effluvium, including beta blockers, oral contraceptives, retinoids, nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin (Indocin) and ibuprofen (Advil), aspirin and other salicylates, lithium, anticoagulants (blood thinners), and anticonvulsants (medications for seizures).

Telogen effluvium usually stops after a few months and new hair grows in. The first regrowth may be finer than usual, but the follicles eventually produce hair of normal thickness.

ANAGEN EFFLUVIUM. Anagen effluvium is a type of diffuse hair loss resulting from a sudden interruption of the growth phase. Unlike the time lag that characterizes telogen effluvium, hair loss in anagen effluvium occurs all at once. The most common cause of anagen effluvium is chemotherapy, including treatment with methotrexate, bleomycin, vinblastine, vincristine, cyclophosphamide, doxorubicin, daunorubicin, and cytarabine. This form of hair loss can also be caused by poisoning with arsenic, thallium, bismuth, or borax.

Anagen effluvium usually stops as soon as the chemical cause is removed, but it may take several months for hair to regrow completely.

Inflammatory nonscarring hair loss

ALOPECIA AREATA. Alopecia areata is a nonscarring recurrent form of hair loss characterized by smooth, round, or oval patches of bare skin. There may be some mild itching but no visible skin eruptions. Alopecia areata is usually considered an idiopathic disorder, which means its cause is unknown. Some researchers, however, consider it an autoimmune disorder. It is often triggered by stress or anxiety. Alopecia areata usually affects only the scalp, the eyebrows, and (in men) the beard, but it may cause hair loss over the entire scalp (alopecia totalis) or even the entire body (alopecia universalis). The loss of hairs from the eyebrows and eyelashes that may be associated with alopecia totalis is called madarosis.

PSORIASIS. Psoriasis is a chronic inflammatory skin disease that frequently affects the elbows and knees as well as the scalp. On the scalp, psoriasis is marked by the appearance of red plaques or patches with silvery scales. These patches may also be found behind the ears. Psoriasis can cause massive but temporary hair loss.

Inflammatory scarring hair loss

In hair loss syndromes marked by tissue scarring, the hair loss is permanent and irreversible. These syndromes should be diagnosed as quickly as possible to minimize the extent of damaged tissue.

LUPUS ERYTHEMATOSUS. Lupus erythematosus is an autoimmune disorder that can affect a number of different organ systems. About 85% of lupus patients are women between 20 and 40 years of age. More than 10% of women with lupus develop a form of the disorder known as chronic discoid or chronic cutaneous lupus erythematosus. Chronic discoid lupus can occur on the scalp as well as the face, and it is marked by dark red patches or plaques between 0.5 in. (1.3 cm) and 0.75 in. (1.9 cm) in diameter. The plaques are covered by dry, horny scales that plug the hair follicles and cause permanent hair loss.

LICHEN PLANOPILARIS. Lichen planopilaris is a form of lichen planus, an idiopathic recurrent skin disorder that usually affects the wrists, legs, and mucous membranes. It is characterized by itching pinkish-red or purplish patches or pimples on the scalp. Like lupus, lichen planopilaris can cause lasting hair loss.

BACTERIAL OR FUNGAL INFECTIONS. Scarring alopecia can be caused by dermatophytes, which are fungi that live on the skin and hair. These fungi include *Trichophyton rubrum*, *Trichophyton tonsurans*, and *Microsporum audouinii*. The dermatophytes infect the skin of the scalp and move down the hair shaft into the follicle, which may be permanently destroyed.

SCLERODERMA. Scleroderma is a chronic disorder in which the patient's skin and connective tissue become progressively thicker and more rigid. Its cause is not known. As the patient's scalp thickens, the hair is gradually but permanently lost.

INJURIES. Scarring alopecia can also result from burns, trauma to the scalp, or radiation treatment.

Genetic profile

Male pattern hair loss (MPHL)

MPHL is a polygenic disorder, which means that its appearance is directed by more than one gene. It may be inherited from either the father's or mother's side. The belief that MPHL is inherited only through the mother is a myth. Genes for baldness are, however, dominant, which means that 50% of the children of a balding parent of either sex will inherit the baldness genes. Studies have shown a link between MPHL and neighboring genes on the X chromosome, including *androgen receptor (AR)* and *ectodysplasin A2 receptor (EDA2R)*, all of which are involved in male pattern baldness. Genetic factors appear

to influence the age of onset of MPHL, the extent and speed of hair loss, and the pattern of hair loss. MPHL may begin at any time after the levels of androgens in a boy's blood begin to rise during puberty.

It is important to note that genes for baldness depend on normal levels of androgen in the body to produce androgenetic hair loss. Men who were castrated prior to puberty or have abnormally low levels of androgen for other reasons do not go bald, even if they have a gene for baldness.

Female pattern hair loss (FPHL)

Female pattern hair loss, or FPHL, is also a dominant disorder. Studies suggest that there is a genetic factor involved, although a genetic mutation has yet to be determined. Studies have also determined a likely correlation between anemia and sex hormones as triggering factors, although they do not indicate a direct relation in terms of severity of the condition.

Alopecia areata

About 20% of cases of alopecia areata are thought to have a genetic component.

Demographics

Androgenetic alopecia

Androgenetic alopecia is quite widespread in the general U.S. population. It is estimated that 35 million American men are affected by this hair loss syndrome. About 25% of Caucasian men begin to show signs of baldness by the time they are 30, and 67% are either bald or developing a balding pattern by age 60. The first evidence of hair loss, namely a receding hairline at the temples, can be found in 96% of Caucasian males over age 15, including those who will not lose any more hair.

There is less agreement on the incidence of androgenetic alopecia among women in the United States: estimates range from 8% to 87%. A commonly accepted figure is that 21 million women are affected. About 80% of girls begin to show some loss of hair at the hairline during puberty, including some who will not develop FPHL.

Alopecia areata

About 2.5 million people in the United States have alopecia areata. It appears to affect men and women equally.

Trichotillomania

Trichotillomania was once thought to be an uncommon disorder, but more recent research suggests that it

occurs fairly frequently among adolescents and young adults. Surveys of college students indicate that 1%–2% are or have been affected by trichotillomania. The male/female ratio is 1:1 in children, but it is about 1:4 in college students. The disorder may be underdiagnosed in males because their hair loss is attributed to MPHL.

Signs and symptoms

The signs and symptoms of each hair loss syndrome are included in its description.

Diagnosis

The differential diagnosis of hair loss is usually made on the basis of the patient's history, visual examination of the scalp, and the results of laboratory tests. The more common forms of alopecia can be diagnosed by a family physician, but those that are related to skin disorders may require referral to a dermatologist. There are four key questions that the doctor will ask in evaluating hair loss:

- How long has the patient been losing hair?
- Is there a pattern to the remaining hair?
- Is the hair loss associated with redness, itching, or pain?
- Are there any patches of broken skin, pimples, plaques, or other signs of infection in the affected areas?

Patient history

The patient's medical history may contain information about previous episodes of hair loss; eating and nutritional habits; use of prescription medications; surgery or chemotherapy; occupational exposure to arsenic, thallium, or bismuth; recent illnesses with high fevers; recent periods of severe emotional stress or anxiety; or other factors that may influence hair loss. In addition, the doctor will ask about grooming habits, including the use of dyes, home permanents, hair straighteners, hair sprays, and similar products, as well as blow dryers, rollers, and other hair styling equipment.

Laboratory tests

Laboratory tests are performed on samples of the hair itself as part of the differential diagnosis. Microscopic study of a hair sample will indicate, for example, damage to the hair shaft, broken hairs, and changes in the shape of the hair. For example, broken hairs may suggest traction alopecia or trichotillomania. In trichotillomania, there will also be an unusually high number of hairs in the catagen phase. Anagen effluvium produces hairs with tapered or pointed ends, sometimes called "pencil-point" hairs. In telogen effluvium, the hairs have white bulbs at the end and can often be removed from the head by very gentle

pulling. In alopecia areata, the area of hair loss is bordered by telltale "exclamation point" hairs.

Hair samples can also be subjected to chemical analysis if heavy metal poisoning is suspected. Arsenic and thallium are absorbed by the hair shaft and can be detected by appropriate tests.

Skin biopsies are most useful in diagnosis when an infection or other inflammatory condition is suspected as the cause of the hair loss. While scarring can often be seen during a visual examination of the scalp, a biopsy may be the only way to tell if the hair follicles have been destroyed, as well as to differentiate among lupus, dermatophyte infection, alopecia areata, and scleroderma. Biopsies may also be useful in determining the presence of traction alopecia or trichotillomania. In these conditions, pieces of hair shaft are sometimes found in the surrounding skin. Some hair follicles may show signs of injury and are interspersed among normal follicles.

Treatment and management

The treatment of hair loss syndromes is determined by their causes.

Medications

TOPICAL APPLICATIONS. Topical applications for hair loss syndromes fall into two major categories—those that stimulate the growth of new hair and those that reduce inflammation. The most frequently prescribed topical medication for male pattern hair loss is minoxidil, which was originally developed to lower high blood pressure. It was approved by the FDA for the treatment of androgenetic hair loss in 1988. Minoxidil, sold under the trade name Rogaine, is applied twice a day as a 2% or 5% solution. It is also sometimes prescribed for female pattern hair loss and alopecia areata. Its chief drawback is its high cost: it costs between \$650 and \$700 a year to use twice a day.

Alopecia areata may be treated with topical corticosteroids or with injections of triamcinolone acetonide (Kenalog) in the affected areas every three or four weeks. Topical corticosteroids are also used to treat chronic discoid lupus, lichen planopilaris, and psoriasis. Tar shampoos are frequently recommended along with topical steroids to treat psoriasis of the scalp.

ORAL MEDICATIONS. One oral medication, finasteride, has been approved by the FDA for the treatment of male pattern hair loss. Finasteride, sold under the trade names Propecia or Proscar, works by interfering with the body's production of 5-alpha-reductase, the enzyme that converts testosterone to DHT. It is considered the most effective nonsurgical treatment of MPHL. The usual daily dose of finasteride is 1 mg. Unlike minoxidil, finasteride does not appear to be effective in postmenopausal

KEY TERMS

Alopecia—Loss of hair or baldness.

Alopecia areata—A nonscarring hair loss syndrome characterized by smooth, round, or oval hairless areas on the scalp.

Anagen—The growth phase of the human hair growth cycle.

Androgens—A group of steroid hormones that stimulate the development of male sex organs and male secondary sexual characteristics.

Catagen—The breakdown phase of the hair growth cycle.

Dihydrotestosterone (DHT)—A male sex hormone formed from testosterone by the enzyme 5-alpha-reductase. DHT causes hair follicles to shut down, shortening the growth phase of the hair growth cycle and leading to miniaturization.

Effluvium—The medical term for massive hair loss or shedding.

Finasteride—An oral medication used to treat male pattern hair loss. Finasteride, sold under the trade names Proscar and Propecia, is an androgen inhibitor.

Keratin—A tough, non-water-soluble protein found in the nails, hair, and outermost layer of skin. Human hair is made up largely of keratin.

Madarosis—The medical term for loss of hair from the eyebrows or eyelashes. Madarosis may be associated with a form of alopecia areata called alopecia totalis. It may also result from such diseases as leprosy and syphilis, or from trauma.

Miniaturization—The process of shortening and thinning of the hair shafts that is found in androgenetic alopecia. It is caused by the effects of DHT on the hair follicle.

Minoxidil—A topical medication sold under the trade name Rogaine for the treatment of male pattern hair loss. It is applied to the scalp as a 2% or 5% solution.

Telogen—The resting phase of the hair growth cycle.

Traction alopecia—Hair loss caused by pressure or tension on the scalp related to certain types of hair styles or equipment worn on the head.

Trichotillomania—A psychiatric disorder characterized by hair loss resulting from compulsive pulling or tugging on one's hair.

Vellus hairs—The fine lighter-colored hairs that result from miniaturization.

women. It has not been tested on women of childbearing age because its androgen content could cause birth defects in male children.

Oral antifungal medications are considered better than topical preparations for treating dermatophyte infections of the scalp because topical products do not penetrate around the hair follicle. The mostly commonly prescribed oral antifungal drugs are griseofulvin (Grisactin, Fulvicin), ketoconazole (Nizoral), and fluconazole (Diflucan).

Clomipramine (Anafranil), which is a tricyclic antidepressant, and fluoxetine (Prozac), a selective serotonin reuptake inhibitor (SSRI), have been used in the treatment of trichotillomania.

Surgery

Surgical transplantation is considered the most effective treatment of MPHL, but it is not recommended for alopecia areata. Punch grafts or larger skin flaps bearing the patient's own hair are transferred from areas of the head with normal hair growth to the balding areas. Hair transplantation is expensive but is usually permanent. It appears to work best on patients with dark or curly hair.

Scalp reduction, in which bald areas at the top of the scalp are removed, is another surgical technique used in treating MPHL. It works best for patients with relatively little hair loss.

Nonsurgical hair additions

These devices consist of human hair, synthetic fibers, or combinations of both. They are added to existing hair or attached to the scalp with adhesives to cover areas of hair loss. They include hair weaves, hair pieces, hair extensions, toupees, partial hair prostheses, and similar devices. Nonsurgical hair additions are less expensive than surgery but still cost between \$750 and \$2,500, depending on materials and design. They can be used in combination with hair replacement surgery.

Psychotherapy

Cognitive-behavioral therapy is considered the most effective form of psychotherapy in treating trichotillomania. Individual psychodynamic psychotherapy is often helpful for persons who are emotionally upset by hair loss, particularly those whose employment depends on their appearance.

QUESTIONS TO ASK YOUR DOCTOR

- Is the hair loss I am experiencing likely to continue, or is it only a temporary problem that will eventually go away?
- Is there any reason to suspect that my hair loss is related to genetic factors? How can I find out one way or another?
- What procedures are available to reduce or reverse the hair loss I have been experiencing?
- Is hair transplantation likely to be an effective method for dealing with my hair loss?

Prognosis

The prognoses of hair loss syndromes vary according to their causes. Hair loss caused by inflammatory scarring has the worst prognosis because syndromes or injuries that form scar tissue destroy the hair follicles, preventing regrowth. The prognosis for alopecia areata is less favorable if the disorder affects large areas of the scalp, begins in adolescence, or has existed for a year or longer before the patient seeks treatment. Alopecia areata that begins in adult life and is limited to a few small areas of the scalp often goes away by itself in a few months, although the condition can recur. Diffuse hair loss related to anagen or telogen effluvium has a good prognosis. Although complete regrowth may take some months, the hair does come back once the cause is identified and removed.

The prognosis for androgenetic alopecia varies. Rogaine does not work equally well for all men with MPHL. Those who benefit most from treatment with Rogaine have been bald for less than ten years, have a bald spot on the crown of the head that is smaller than 4 in. (8cm) across, and still have vellus hairs in their balding areas. Hair that grows in as a result of Rogaine will fall out once the patient stops using the medication. Finasteride is becoming the first-line nonsurgical treatment for MPHL because it prevents hair loss as well as aids regrowth; one study indicates that finasteride prevents further loss of hair in 90% of men even five years after they take it, and it assists regrowth in 65% of men even two years later.

Hallermann-Streiff syndrome

Definition

Hallermann-Streiff syndrome is a rare genetic condition that causes characteristic facial features, visual abnormalities, tooth problems, short stature, and, occasionally, mental impairment.

Description

Hallermann-Streiff syndrome is also known as François dyscephaly syndrome, Hallermann-Streiff-François syndrome, oculomandibulodyscephaly with hypotrichosis, and oculomandibulofacial syndrome. The distinctive facial features of Hallermann-Streiff syndrome include a very small head that is unusually wide; a prominent forehead; a small, underdeveloped jaw; an unusually small mouth; and a characteristic beak-shaped nose. Small eyes, clouding of the lens of the eyes (cataracts), and other eye problems often leading to blindness are common. Problems with the teeth, skin, hair, and short stature are also common. Most individuals are of normal intelligence, but mental impairment has been reported in some. Most cases of Hallermann-Streiff syndrome occur randomly for unknown reasons and may be the result of mutations, or changes to the genetic material.

Genetic profile

Hallermann-Streiff syndrome is a genetic condition. Genes are units of hereditary material passed to a child

by his or her parents. The information contained in genes is responsible for the growth and development of all the cells and tissues of the body. Most genes occur in pairs: one copy of each pair is inherited from the mother through the egg cell and one copy of each pair is inherited from the father through the sperm cell. If there is a gene alteration (mutation), this may interfere with normal growth and development. The specific gene responsible for Hallermann-Streiff syndrome has not yet been identified.

Most cases of Hallermann-Streiff syndrome occur randomly in families with no other affected individuals. In this situation, the gene alteration is a spontaneous mutation. This means that some unknown event has caused the gene (which functions normally in the parent) to change in either the father's sperm or the mother's egg from which the affected individual was conceived. A person who has Hallermann-Streiff syndrome due to a spontaneous mutation can pass on this mutated gene to offspring who will also be affected. The chance for someone with Hallermann-Streiff syndrome to have a child with the same condition is 50% in each pregnancy. There is also a 50% chance to have a child who is not affected with Hallermann-Streiff syndrome.

There are some reports in the literature that indicate that Hallermann-Streiff syndrome is inherited as a recessive condition. Recessive conditions occur when both copies of a gene pair are changed. The affected individual inherits one mutated gene from each parent. The parents of the affected individual are carriers for one changed copy of the gene pair but are not affected themselves. Carrier couples have a 25% chance in each pregnancy to have a child affected with the condition. Diagnosed individuals are at risk to have an affected child only if their partner is also affected or is a carrier. There is no clear agreement on whether Hallermann-Streiff syndrome can be inherited as a recessive condition. Some have argued that the families reported to have recessive Hallermann-Streiff syndrome in fact do not have this condition but some other condition with features very similar to Hallermann-Streiff syndrome.

Demographics

Hallermann-Streiff syndrome affects both males and females in all ethnic groups. There have been over 150 cases reported in the literature.

Signs and symptoms

Hallermann-Streiff syndrome affects the face, skull, hair, skin, eyes, teeth, and overall growth and development.

Face and skull

The facial features of individuals with Hallermann-Streiff syndrome are distinctive. The face is small with a thin, tapering, pinched nose and small chin. The head is small and unusually wide with a prominent forehead; a small, underdeveloped jaw; and a small mouth. Characteristic changes in the bones of the skull and the long bones of the arms and legs can usually be seen on x-ray. The hair is usually sparse, particularly that of the scalp, brows, and lashes. Often there is no hair around the front and sides of the head. The skin of the scalp is thin and taut, and scalp veins are prominent.

Potential complications in Hallermann-Streiff syndrome are related to the narrow upper airway associated with the shape of the skull, particularly the small chin, mouth, and nose. The narrow air passages may result in feeding difficulties and mild aspiration of food. This can lead to severe complications including early lung infection and breathing difficulties. The lung infection can be life threatening. Some individuals may experience a temporary stop in breathing during sleep because of an obstruction caused by the shape of the skull (obstructive sleep apnea). Individuals with Hallermann-Streiff syndrome are also at increased risk of breathing difficulties when given a general anesthetic before surgery.

Eyes

Individuals with Hallermann-Streiff syndrome may be born with clouding of the lenses of the eyes (congenital cataracts). Congenital cataracts are the most common eye disorder and are usually the reason for a visit to the eye specialist in early life. The cataracts have been reported to spontaneously disappear in some cases. The second most common eye problem is that the eyes are unusually small. Other eye problems may include rapid, involuntary eye movements; crossing of the eyes and/or decreased visual clarity; and, in some cases, blindness.

Teeth

Dental problems are very common. They may include the presence of teeth at birth and the presence of extra teeth. Underdevelopment of tooth enamel and cavities are also common. There may also be absence, malformation, and/or improper alignment of certain teeth.

Growth and development

Most individuals with Hallermann-Streiff syndrome are born at term, but about one-third are born premature and/or have a low birth weight. Short stature is seen in about half of the individuals with Hallermann-Streiff syndrome. The average final height is about 60 in. (152 cm) for females and 61 in. (155 cm) for males.

KEY TERMS

Anesthetic—Drug used to temporarily cause loss of sensation in an area of the body. An anesthetic may either be general, associated with a loss of consciousness, or local, affecting one area only without loss of consciousness. Anesthetics are administered either via inhalation or needle injection.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual or manifest as disease and can be transmitted to offspring.

Trachea—Long tube extending from the larynx down into the lungs, responsible for passing air.

Tracheostomy—An opening surgically created in the trachea (windpipe) through the neck to improve breathing.

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

Most individuals are of normal intelligence; however, it is estimated that 15%–30% of individuals with Hallermann-Streiff syndrome show some degree of mental impairment or slow development. Hyperactivity and seizures have been reported in a small number of individuals.

Other

A small number of individuals with Hallermann-Streiff syndrome have heart defects (such as a hole in the heart). There has also been a report of an individual with a weakened immune system.

Diagnosis

The diagnosis of Hallermann-Streiff syndrome is based on the presence of certain features including the characteristic facial, eye, dental, hair, and skin findings. The main features indicative of Hallermann-Streiff syndrome include a small, wide head with a prominent forehead; the characteristic small jaw and mouth with a pinched nose; cataracts; small eyes; dental abnormalities; sparse or absent hair; thin skin; and short stature. X-rays of the bones of the body may be helpful in establishing a diagnosis of Hallermann-Streiff syndrome because there are characteristic changes evident in the bones of individuals with this condition. There is no laboratory test that can be done to confirm the diagnosis. Genetic testing

to identify the specific genetic alteration causing the condition is not available since the gene for Hallermann-Streiff syndrome has not been identified. Testing for Hallermann-Streiff syndrome in an unborn baby has not been done. It may be possible to detect the abnormal head shape and small chin on an ultrasound of the developing baby, but this has not been documented in the literature.

Treatment and management

There is no cure for Hallermann-Streiff syndrome. In general, an individual with Hallermann-Streiff syndrome requires a team of specialized doctors for treating the various problems that can occur. Assessments by a dentist, dental surgeon, and oral-facial surgeon may also be necessary to evaluate the teeth and difficulties caused by the small chin and mouth. An assessment for possible airway problems is essential. Any individual with Hallermann-Streiff syndrome who shows signs of daytime sleepiness or snoring should be referred to a sleep center for proper diagnosis and treatment of possible obstructive sleep apnea. Treatment for this condition may include surgical procedures, such as making a hole in the trachea through the neck to relieve whatever is obstructing the breathing (tracheotomy). Other surgical treatments may include advancing the chin, reducing the size of the tongue, and/or removing the tonsils. Nonsurgical treatments may include medications, providing the individual with an oxygen mask, and modifying his or her sleeping position.

An individual with Hallermann-Streiff syndrome should be examined by an eye specialist (ophthalmologist) for signs and symptoms of eye problems. Surgery for some types of eye problems (cataracts, crossed eyes) may be necessary. Individuals who are blind or at risk of losing their eyesight may benefit from being referred to an association for the blind for guidance and counseling.

An examination by a heart specialist (cardiologist) for possible heart problems and by an immune specialist (immunologist) for possible decreased immune function is also recommended. Some types of heart problems may be treated with medications or may require surgical correction.

For individuals with developmental delay or mental impairment, treatment may include special education, speech therapy, occupational therapy, and physical therapy. Drugs may be used to treat hyperactivity, seizures, and other problems.

Some individuals with Hallermann-Streiff syndrome may seek cosmetic surgery for the various effects the syndrome has on the face and skull. Counseling by psychologists may also help individuals with Hallermann-Streiff

QUESTIONS TO ASK YOUR DOCTOR

- How is it possible to predict the possible occurrence of Hallermann-Streiff syndrome in a family?
- What are the physical characteristics on which a diagnosis of Hallermann-Streiff syndrome is based in a young child?
- What types of treatment are available for the disorder, and how effective are those treatments?
- What patient-support organizations are available for families with a Hallermann-Streiff child?

syndrome cope with the psychological impact of having a facial difference.

Individuals with Hallermann-Streiff syndrome and their families may also benefit from genetic counseling for information on the condition and recurrence risks for future pregnancies.

Prognosis

Individuals diagnosed with Hallermann-Streiff syndrome typically have normal intelligence and life-spans when complications of this disorder are properly managed. A major difficulty for individuals with Hallermann-Streiff syndrome is that the visual problems can often lead to blindness, despite surgery. Lung infections can be life threatening to these patients and must be treated immediately. Breathing problems are another serious complication resulting from the abnormal skull formation that narrows the upper airway. Although uncommon, developmental delay and mental impairment have been reported in a minority of individuals affected with Hallermann-Streiff syndrome. These individuals with significant mental impairment may require lifelong supervision.

Hand-foot-genital syndrome

Definition

Hand-foot-genital (HFG) syndrome is a very rare genetic disorder that affects the development of the hands, feet, urinary tract, and reproductive tract.

Description

The hallmarks of HFG include incurving of the fingers (clinodactyly) and shortened and relocated thumbs. There are also wrist- and ankle-bone fusions, very small feet, short great toes, urinary-tract abnormalities, duplications of the reproductive tract in women, and urethral openings on the underside of the penis and a curved penis in men. HFG was first described in 1970 as hand-foot-uterus (HFU) syndrome. Based on the findings of genital abnormalities in affected males, a 1975 study suggested that HFG was the more accurate name. Although people with HFG are usually fertile, because of problems with early uterine development, some women are at increased risk for pregnancy loss, premature labor, and stillbirth.

Genetic profile

HFG is caused by autosomal dominant mutations in the *HOXA13* gene, which stands for "homeobox A13." Autosomal dominant means that only one altered *HOXA13* gene—inherited from one parent—is required for HFG to develop, even in the presence of a normal

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Clinodactyly—An abnormal inward curving of the fingers or toes.

HOXA13 gene inherited from the other parent. In some cases, rather than being inherited from a parent, HFG is caused by *de novo* (new or sporadic) *HOXA13* mutations that occur in the sperm or egg or during early embryonic or fetal development. In such cases, there is no family history of the disorder.

HOXA13 is located on the short arm (p) of chromosome 7 at position 15.2 (7p15.2). *HOXA13* is a member of a gene family known as *homeobox* genes. It produces a protein called a transcription factor that binds to specific regions of DNA to regulate the activity of other genes. *HOXA13* is critical during embryonic development, especially for the formation of the hands and feet and the urinary tract and reproductive system.

Different mutations in the *HOXA13* gene result in different signs and symptoms or phenotypes of varying severity. The *HOXA13* gene contains three regions that code for strings of the amino acid alanine in the protein. Many of the HFG-causing mutations add extra alanines to these strings, making them abnormally long and unstable. *HOXA13* proteins with these extra alanines are degraded by the cell and are not available for developmental functions. Other identified mutations in *HOXA13* include “nonsense” mutations that result in a shortened nonfunctional *HOXA13* protein. Some mutations change single amino acids within the *HOXA13* protein, resulting in an abnormal protein that interferes with normal functioning within the cells of the developing fetus. These mutations that lead to an altered protein appear to cause more severe signs and symptoms than mutations that lead to a nonfunctional protein.

Demographics

HFG syndrome is extremely rare. Worldwide, there are only a few families who have been identified with HFG.

Signs and symptoms

HFG affects the hands, feet, and urinary and reproductive tracts, although the abnormalities and their severity

vary, even in individuals in the same family. HFG causes abnormal thumbs and small feet with short big toes. Females have duplications within the genital tract. Many affected individuals have defects in the ureters, which transport urine from the kidneys to the bladder; others have defects in the urethra, through which urine exits the body. These abnormalities can result in frequent urinary tract infections or urinary incontinence (inability to control urination). About half of affected males have the urethra opening on the underside of the penis.

Diagnosis

Diagnosis of HFG is usually made with a physical examination by a medical geneticist and x-rays or other imaging of the hands, feet, and reproductive and urinary tracts. Genetic testing for HFG may be available by sequencing the entire coding region of the *HOXA13* gene or deletion/duplication analysis of the gene.

Treatment and management

There is no specific therapy that can repair all of the effects of HFG syndrome, but surgery can alleviate some abnormalities. Management focuses on treating specific effects of the disorder.

Prognosis

Because the signs and symptoms of HFG vary considerably, the prognosis for affected individuals varies. Most people with mild or moderate hand, foot, and/or genital abnormalities lead relatively normal lives. Severe urinary- and/or reproductive-tract abnormalities may require multiple surgeries with prognoses depending on the severity of the abnormalities and success of the surgeries. Some people with severe reproductive-tract abnormalities may have difficulty having children.

Harlequin ichthyosis

Definition

Harlequin ichthyosis (HI) is a very severe skin disorder in which infants are born with thick, plate-like scales all over their bodies. HI can result in facial disfigurement and limited movement of the arms, legs, fingers, and toes. In the past, affected infants died during the first weeks of life, but improved treatments have significantly increased survival rates.

Description

HI represents the most severe presentation of congenital ichthyosis. It is also known as autosomal recessive

congenital ichthyosis 4B (harlequin) or ARCI4B. The term "ichthyosis" is derived from the Greek word for "fish." Ichthyoses are a family of more than 25 types of skin disorders characterized by markedly thickened, ridged, and cracked skin. They are caused by various underlying genetic abnormalities of metabolism that result in defective keratinization, which is the process in which new epidermal cells of the outermost layer of skin are gradually changed into the stratum corneum. The layers of dead cells of the stratum corneum are filled with keratin protein and act as a protective barrier over the surface of the body. This process is controlled by a number of different metabolic pathways, and an abnormality at any point can theoretically lead to conditions such as ichthyosis or other serious skin abnormalities.

The types of ichthyoses are defined by their clinical features, the age at which symptoms appear, and their underlying genetic cause. Ichthyosis of the newborn is present at birth or shortly thereafter and can be caused by several different genetic abnormalities, even when there is some similarity in the clinical features. HI, however, is such a distinct and striking disorder that it is rarely confused with other types of ichthyosis. HI was previously known as harlequin fetus. Affected infants have thick, armor-like skin with deep cracks running in different directions all over their bodies. This gives the appearance of diamond-shaped plaques; thus, the descriptive term "harlequin." This severe skin abnormality leads to an open, "fish-mouthed" appearance and a turning outward of the eyelids. Abnormalities of the internal organs are uncommon but have been reported. Early death from severe skin infection is common because the abnormal skin does not form a proper barrier between the body and the environment.

Genetic profile

HI is inherited as an autosomal recessive condition. This means that an affected child has inherited two copies of a defective gene—one from each parent. In most cases, the parents are carriers with one defective and one normal gene and no symptoms of the disorder. If each parent is a carrier, there is a one in four chance that each of their children will have HI and an additional 50% risk that each child will inherit one gene for HI and be a carrier.

HI is caused by mutations in the *ABCA12* gene located on the long arm (q) of chromosome 2 at position 2q35. *ABCA12* stands for "ATP-binding cassette subfamily A member 12." The HI mutation inherited from each parent may be the same or different changes within the *ABCA12* gene. *ABCA12* is believed to produce a protein that plays a major role in the transport of lipids (fats) across cell membranes in the epidermis and is essential for the normal development of skin cells. *ABCA12*

Harlequin fetus is a severe and usually fatal form of ichthyosis. This rare skin disorder results in thick, scaly skin; turning out of the eyelids (ectropion) and the lips (eclabium); and deep skin fissures. (Gale)

mutations can lead to no protein at all or to a shortened protein that cannot properly transport lipids. This prevents normal skin development and results in hard, thick, scaly epidermis—hyperkeratosis.

More than 55 different *ABCA12* gene mutations that cause HI have been identified. These include different-sized deletions within the *ABCA12* gene. All of the HI-causing mutations prevent production or functioning of the transporter protein. If the *ABCA12* gene mutations in an affected family have been identified, prenatal testing and carrier testing of at-risk relatives are available. Other mutations in *ABCA12* can cause a different form of ichthyosis called lamellar ichthyosis.

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Carrier—An individual who possesses an unexpressed abnormal gene of a recessive genetic disorder.

Eclabium—Outward turning of the lip.

Ectropion—An abnormal turning out, as of the eyelid.

Epidermis—The outermost layer of the skin.

Hyperkeratosis—Abnormal thickening of the outermost layer of the skin, the stratum corneum.

Keratinization—The conversion of the epidermis into the stratum corneum.

Pathogenic variant—A mutation or variation in a gene that causes a genetic disorder.

Stratum corneum—The outer portion of the epidermis made up primarily of dead, flattened cells filled with the protein keratin.

Demographics

HI is a very rare form of congenital ichthyosis. It is estimated to affect about 1 in every 200,000 births in the United States or about 19 newborns per year. Like other autosomal recessive conditions, HI is more common among the children of consanguineous (related) couples, such as first cousins. Biologically related individuals are much more likely to carry the same recessive gene and, hence, have offspring with autosomal recessive disorders.

Signs and symptoms

Infants affected with HI have a unique and striking appearance at birth. Their skin is unusually thick, off-white in color, and resembling “armored” scales separated by deep, moist cracks running in different directions. The facial appearance is distorted with marked ectropion or turning outward (eversion) of the eyelids. The lips also turn outward (eclabium). The external ears are absent or flattened against the side of the head, and the nose is flattened. The hands and feet are grayish-white in color. The fingers and toes appear malformed due to impeded blood circulation from the constrictions that can cause tissue death (necrosis). Nails and body hair may be missing. There is limited mobility of the arms and legs due to the scaly plates and constrictions. Abnormalities of the central nervous system, kidneys, and lungs

QUESTIONS TO ASK YOUR DOCTOR

- What treatments are available for harlequin ichthyosis?
- What is the prognosis for my child with harlequin ichthyosis?
- Can my partner and I have genetic testing for the gene that causes harlequin ichthyosis?
- What are the chances that we will have a second child with harlequin ichthyosis?
- Is preimplantation or prenatal testing available for harlequin ichthyosis?

have been described in some affected individuals. Short stature has been observed in survivors. However, because the protective barrier of the skin is severely compromised, newborns are at serious risk for systemic infection (sepsis), dehydration, and poor temperature regulation.

Diagnosis

HI may be diagnosed by clinical examination after birth; however, a skin biopsy may be necessary to confirm a diagnosis of this particular type of ichthyosis. A sample of skin is examined under an electron microscope for the characteristic changes of hyperkeratosis (overgrowth of the stratum corneum). Prenatal diagnosis of HI can be performed by genetic testing for *ABCA12* gene mutations, microscopic analysis of cells from a sample of amniotic fluid, or biopsy of the fetal skin. This is usually accomplished by a combination of fetoscopy and amniocentesis. The cellular changes associated with hyperkeratosis begin during the latter part of the second trimester of pregnancy—21–23 weeks gestation, possibly earlier. Prenatal ultrasound alone will not detect many of the features associated with HI, particularly in a low-risk patient population.

Treatment and management

Infants with HI tend to be born prematurely. Thus, if HI has been diagnosed prenatally and the pregnancy is continued, the mother should undergo close monitoring for the remainder of her pregnancy. Most deaths from HI occur in the first few days after birth. Immediate care of a newborn with HI focuses on control of body temperature and prevention of dehydration, malnutrition, and infection. Infants who are born prematurely may require a breathing tube, as well as intravenous fluids, nutrients, and antibiotics. Medication for pain management should

be provided as needed. Sponge baths or tub soaking and the application of skin moisturizers with antibiotics should be performed twice daily to soften the skin, reduce scaliness, and prevent infection. The oral retinoids isotretinoin or etretinate also loosen and help shed the scales. Artificial tear treatments may be required for infants with severe ectropion.

Prognosis

In the past, most infants with HI died within a few days of birth. However, advances in neonatal care, and perhaps etretinate treatments, have increased survival rates. Common causes of death include respiratory complications due to prematurity or constriction by the thick scales that causes dehydration or skin infection. Among survivors, the ichthyosis does not go away, but large, thin scales covering dry, reddish skin gradually replace the cracked, thick skin. Hair may be sparse. The eversion of the eyelids and lips gradually resolves. Physical development may be slow due to the enormous caloric requirement for skin functioning. An extensive skincare program must be maintained to keep the skin pliable and moist and prevent fissuring and cracking that can lead to infection. Mental development is usually normal. However, sudden death may occur even with attentive medical care. As of 2015, several individuals with HI had survived into their teens and 20s. In 2013, a young woman with HI gave birth to a healthy baby.

HeLa cells

Definitions

HeLa cells refer to the oldest and best-known immortal cell line used in biomedical research. An immortal cell line is a population of cells that has evaded normal cellular senescence (the ending of cellular replication) and can continue to reproduce indefinitely, usually as the result of a mutation. The name *HeLa* (pronounced HEE-la) was formed from the first two letters of the first and last names of Henrietta Lacks, the terminally ill patient who provided the cervical tissue used to start the cell line during her treatment for cancer in 1951.

Description

The patient

Henrietta Lacks (1920–1951) was a 31-year-old African American woman living in Baltimore, Maryland, who noticed unexplained vaginal bleeding shortly after the birth of her fifth child. She went to Johns Hopkins Hospital in January 1951 for examination, as it was the only hospital in the area that treated Black patients. Her surgeon biopsied a mass that he found on her cervix; it was an adenocarcinoma of the cervix, a particularly aggressive form of cervical cancer.

There were very few treatments for cervical cancer in the early 1950s. Lacks was initially treated with brachytherapy, a type of cancer treatment in which a sealed source of radiation is placed in or near the area to be treated. While she was an inpatient, two samples of her cervical tissue, one healthy and one cancerous, were removed without her knowledge or consent. This taking of tissue samples from hospital patients was standard practice in the 1950s, however, and was done without regard to the

patient's age, sex, race, or income level. Lacks' samples were given to the cell biologist George Otto Gey (1899–1970; name is pronounced *guy*), the director of the Tissue Culture Laboratory at Johns Hopkins Hospital.

After several months of outpatient X-ray therapy, Lacks returned to the hospital in early August 1951 with severe abdominal pain; she remained there until her death on October 4, 1951. Her autopsy showed that the cancer had spread throughout her body. A detailed description of her autopsy published in 2009 indicated that her chest and abdominal cavities were filled with cancerous tumors, and her ovaries and fallopian tubes had been completely destroyed by the cancer.

The laboratory

Gey's Tissue Culture Laboratory at Johns Hopkins Hospital was small and underfunded compared to today's large and well-furnished biomedical laboratories. The laboratory was given about \$5,000 per year in 1951, a sum equivalent to \$51,770 in 2021. Gey, who was particularly interested in cancer research, had only two assistants: his wife Margaret, a registered nurse; and Mary Kubicek, a recent college graduate with a degree in physiology. Kubicek used Gey's roller-tube technique to incubate the cells from Lacks' cancerous biopsy specimen. Unlike previous attempts to culture cervical cancer cells in the laboratory, Lacks' cells grew vigorously, dividing every 20 to 24 hours, and showed no signs of cellular senescence. The cells, named HeLa (for Henrietta Lacks), were incubated in a mixture of chicken plasma, bovine embryo extract, and human placental cord serum, according to an article published in *Cancer Research* by Gey and Kubicek in 1952.

Neither Gey nor Johns Hopkins Hospital was interested in profiting from the sale of the HeLa cells. As the founder of the Tissue Culture Association (now the Society for In Vitro Biology), Gey donated the cells freely to other researchers for what he considered their benefit to science. Later, however, a number of scientists and laboratories did make money from the sale of HeLa cells—which prompted a controversy that continues to the present day and will be discussed below.

Distinctive features of HeLa cells

Advances in both technology and laboratory technique enabled researchers in the early 2000s to discover several features of HeLa cells that explain their immortality as well as their distinctive genome. In 2007, a team of researchers found that HeLa cells express telomerase, an enzyme that prevents telomere shortening during the process of cell division. Telomeres are repeated DNA sequences that cap the ends of chromosomes and protect

chromosomal stability. In normal cells, the telomeres are shortened each time the cell divides until they reach a critical length known as the Hayflick limit. At that point (between 40 and 60 cell divisions) the cell stops dividing and enters senescence. In contrast, the telomeres of HeLa cells are not shortened during cell division, and consequently the cells evade the Hayflick limit.

The HeLa genome is unusual in several respects. It resulted from horizontal gene transfer from human papillomavirus (HPV) 18 to the original cervical cancer cells, leading to an uncommonly high total number of chromosomes. Present cytogeneticists define the HeLa chromosome number as hypertriploid, meaning that each HeLa cell contains more than three times the normal haploid number of human chromosomes, which is 23. Some HeLa cells contain as many as 76 to 80 chromosomes. Repeated karyotyping has shown that this unusual genome has remained stable even after years of cell culture.

Purpose

The HeLa cells are considered a landmark contribution to biomedical research and have led to numerous discoveries; over 110,000 articles that involved the use of HeLa cells were published in medical journals between 1952 and 2018. Immortal cell lines are important in medical research because they guarantee that the cells from a given line are homogeneous (identifiably the same throughout a specific experiment), and that a given experiment can be replicated (reproduced) by other scientists using the same cell line to verify the accuracy of the first group's results.

A lasting problem with the HeLa cells that could not have been foreseen in 1951, however, was that their immortality turned out to include the colonization and contamination of other cell lines. The cells' invasiveness led to a major scientific crisis in the late 1960s and early 1970s. A cell biologist named Stanley Gartler (1923–), then at the University of Washington, published an article in *Nature* in 1968 showing that 19 other cell lines thought to be unique had in fact been cross-contaminated by HeLa cells, most likely as a result of poor laboratory storage and handling techniques.

Gartler's work, which used enzyme biomarkers, was followed up by Walter Nelson-Rees (1929–2009), a cytogeneticist who worked in what was then the Naval Biosciences Laboratory (NBL) in Oakland, California. The cell culture laboratory within the NBL was funded by the National Cancer Institute (NCI) to establish, store, and distribute cell lines to researchers around the world. Nelson-Rees used Giemsa staining to mark the banding patterns on chromosomes rather than Gartler's enzyme

profiles; this change in method enabled him to uncover a much larger number of supposedly independent cancer cell lines that had been contaminated by HeLa cells during their use as model systems for studies on breast, prostate, ovarian, and various other cancers. Nelson-Rees' findings meant that any organ- or tissue-specific studies based on the contaminated cell lines were useless. One writer estimated that at least 500 publications had been invalidated and over \$20 million in research funding had been wasted between 1975 and 1981. Nelson-Rees retired in 1981 before the application of molecular methods to cell line verification, but the newer technique of forensic DNA fingerprinting has confirmed the accuracy of his work.

Early HeLa research

HeLa cells played an important part in the following discoveries:

- 1953: Jonas Salk (1914–1995) begins clinical trials of his killed-virus polio vaccine. George Gey notes in the same year that HeLa cells are useful in testing a polio vaccine because the cells are easily infected and killed by the poliovirus. To obtain enough cells for testing Salk's vaccine, a cell culture "factory" is opened at Tuskegee University in Alabama for mass production of HeLa cell lines. At its peak, the Tuskegee team is shipping 20,000 tubes of HeLa cells per week to various laboratories.
- 1953: Theodore Puck (1916–2005) and Philip Marcus (1927–2013) successfully clone HeLa cells, making them the first human cells to be cloned.
- 1955: Joe Hin Tjio (1919–2001; pronounced CHEE-oh) makes use of a laboratory error in which HeLa cells were mixed with the wrong liquid to make an accurate count of the normal number of chromosomes in humans. Scientists had thought that there are 24 pairs of chromosomes in human cells since 1921, when the first attempt was made to count them; Tjio showed that there are only 23 pairs.
- 1964: HeLa cells are sent into space on satellites and manned space missions to evaluate the long-term effects of space flight on living tissues. It is found that HeLa cells divide even more rapidly than usual in zero gravity.

HeLa research after 1968

Gartler's and Nelson-Rees' discovery of HeLa cells' cross-contamination of other cell lines did not hinder ongoing work with the cells:

- 1983: Harald zur Hausen (1936–), a German cancer researcher, identifies the DNA of human papillomavirus 16 in human cervical cancer tumors, followed by identification of HPV 18 in these cancers a year later—the first time that a researcher shows that a viral

- infection can cause cancer. Zur Hausen also demonstrates that HPV 18 infection caused the aggressive cancer that killed Henrietta Lacks. A vaccine effective against HPV was developed in 2006.
- 1988: Researchers discover that HeLa cells are not easily infected by HIV; this discovery in turn leads them to gain a better understanding of how HIV infection actually proceeds.
- 2001: Researchers in the field of veterinary medicine use HeLa cells to study how parvoviruses, which cause severe infections in cats and dogs, gain entrance to and replicate in animal cells.
- 2009: Elizabeth Blackburn, Carol Greider, and Jack Szostak receive the 2009 Nobel Prize in Physiology or Medicine for their discovery of the enzyme telomerase in HeLa cells and its role in their immortality.
- 2019: A team of researchers at the University of Texas Medical Branch at Galveston shows that the Zika virus will not multiply in HeLa cells.

Controversies

HeLa cells have been at the center of several major controversies about the doctor/patient relationship, equal access to health care, patient privacy, and the use of patient samples in for-profit medical research. These controversies have arisen as a result of technological, social, communications, and legislative changes in the 70 years since Henrietta Lacks' death in 1951. Some key dates that provide a historical perspective on these changes include the following:

- Passage of the Civil Rights Act of 1964, which prohibits unequal application of voter registration requirements, racial segregation in schools and public accommodations, and employment discrimination.
- 1969: The first computers are connected to ARPANET, the forerunner of the Internet.
- 1973: Introduction of the first handheld cellular phone.
- 1974: Introduction of the first true personal computer.
- 1985: First use of DNA profiling to identify an individual to solve a murder case in the United Kingdom.
- 1990: In *Moore v. Regents of the University of California*, the Supreme Court of California rules that a patient's discarded blood and tissue samples are not the patient's personal property, and that individuals cannot claim a share of the profits earned by commercialization of their cells.
- 1997: SixDegrees is launched as the first social media platform; Facebook follows in 2004.
- 2003: The work of the Human Genome Project is declared complete.

- 2013: German researchers at the University of Heidelberg publish the HeLa genome.
- 2021: The Henrietta Lacks Enhancing Cancer Research Act of 2019 is signed into law as Public Law 116-291.

Ownership of human tissue samples

The case of *Moore v. Regents of the University of California* set an important precedent for patients seeking financial compensation for researchers' or pharmaceutical companies' commercialization of their biospecimens. John Moore was a California man whose leukemia cells were later developed into a cell line by his physician and by UCLA. Since this 1990 case, most courts in the United States have ruled against family members who sue researchers and universities over the improper commercialization of a dead relative's biospecimens.

A major reason for rising discontent with the 1990 California decision is the vast sums of money involved in contemporary biomedical research compared with funding in the 1950s. One illustrative example is the difference between the \$5,000 that George Gey was given to work with at Johns Hopkins in 1951 and the \$6.9 billion budget of the National Cancer Institute in 2020. To quote the author of an article published in *Johns Hopkins Magazine*, Henrietta Lacks' family came to believe that "someone somewhere is making a lot of money off of drugs and biological products that were developed using pieces of tissue from people who now are entitled to a piece of the profits." One of the tragic aspects of the family's story is that Lacks' descendants had difficulty affording even basic health care until the publication of Rebecca Skloot's 2011 book about the HeLa cells, *The Immortal Life of Henrietta Lacks*.

Informed consent

Informed consent refers to a process in which a health care provider obtains a patient's permission before performing a medical or surgical intervention, before enrolling a person in a clinical trial or other form of research, or before disclosing personal health information (PHI). The health-care provider must make sure that the patient understands the nature of the procedure or research, including its risks as well as possible benefits; and that he or she is not intoxicated or suffering from a mental disorder or disability. This safeguard did not exist in the 1950s, as medical research did not then involve shared decision-making between practitioner and patient.

In 1981, the Common Rule was instituted in the United States as a federal code of ethics governing the protection of human subjects in medical research. The rule stipulates the importance of obtaining subjects' informed consent; specifies the provision of institutional

review boards (IRBs) in all institutions conducting research with human subjects; and requires additional protections for such vulnerable subjects as pregnant women, fetuses, children, and prisoners. At present, Johns Hopkins and other university-related medical centers ask patients to sign a consent form giving the institution permission to use tissue samples provided that the school “may only use or disclose tissues or parts that identify [the patient] for research with [his or her] permission or with approval of a review board governed by federal laws protecting these activities. If the tissues or parts do not identify [the patient], Johns Hopkins may use them for scientific (research) purposes without [his or her] permission or action by a review board.”

A major complication with informed consent in 2021, however, is the rapid growth in genomics as well as other technological changes speeding up biomedical research. One consequence is that neither patients nor researchers can foresee how biospecimens donated in 2021 might be used in research in 2031. Henrietta Lacks’ physicians could not possibly have anticipated the many uses to which the HeLa cells have been put since 1951. An ongoing ethical issue with informed consent is how much flexibility researchers should be given in using previously donated biospecimens, or whether there should be tighter regulation of future research.

Patient privacy

George Gey never disclosed Henrietta Lacks’ identity; to protect her, he named her cell line according to the convention common in the 1950s, of using the first two letters of her first and last names. Until the 1970s, researchers using the HeLa cells assumed that the donor’s name was either Helen Lane or Helen Larson. Lacks’ privacy was breached, however, in 1976, when a team of Johns Hopkins geneticists contacted the Lacks family in order to obtain blood samples from Henrietta’s widower and children. The reason for the blood draws was to obtain DNA markers that could identify HeLa cells in any laboratory sample. Then Victor McKusick (1921–2008), the leader of the Hopkins team, published an article in *Science* in January 1976, in which he not only described the genetic characteristics of HeLa cells but identified Lacks and referred to her other family members as “Husband,” “Child 1,” and “Child 2.” No reputable geneticist would use such identifiers in 2021; in addition, biospecimens are now identified only by code numbers rather than letters or initials.

Another violation of privacy occurred in 1985, when someone at Johns Hopkins gave copies of Lacks’ medical records to Michael Gold, a journalist who published a book in 1986 about Walter Nelson-Rees’ investigation of cell lines that had been cross-contaminated by HeLa

cells. Gold included a detailed description of Lacks’ autopsy in his book.

The turning point occurred in 2013, when a group of geneticists at the University of Heidelberg in Germany published the complete genome of a HeLa cell in the journal *G3* without the knowledge of the Lacks family. When the Lacks family objected, the German scientists voluntarily withheld access to the sequence data. Francis Collins, the director of the NIH, then worked with the family to arrive at an agreement announced in August 2013. Access to the HeLa genome is as of 2021 controlled by a committee that includes two members of the Lacks family as well as four scientists and ethicists. Researchers seeking access to the genome must demonstrate to the committee’s satisfaction that the proposed study is for medical research and that the users will abide by the terms of the HeLa Genome Data Use Agreement.

Underserved populations

Given the social and political changes that have taken place since 1951 in the United States in regard to race relations, Henrietta Lacks’ situation as an African American woman in a city that still practiced racial segregation in 1951 has attracted the attention of current historians as well as medical researchers. Jonas Salk’s decision to secure HeLa cells for testing his polio vaccine from Tuskegee University, a historically Black institution, was an early step toward progress.

In 2010, Johns Hopkins began to host two annual symposia in honor of Henrietta Lacks, one focusing on medical ethics and the other on research using HeLa cells. In 2011, the university established a four-year scholarship in Lacks’ name for a graduate of a local high school pursuing a career in the health sciences. In May 2014, the Brooklyn Public Library in New York held a special event for students and educators titled “We Speak Your Name: Exploring the Life of Henrietta Lacks,” sponsored by the Smithsonian’s National Museum of African American History and Culture and the NHGRI. The Brooklyn event led to the development of four high school–level lesson plans exploring the ongoing significance of Lacks’ life and experiences for understanding health disparities in the present-day American population.

The publication of Rebecca Skloot’s book on Henrietta Lacks’ cell line reopened a nationwide conversation on the relationship between biomedical research, the American health care system, and the need to improve health care for historically underserved groups. The definition of such groups, however, is changing as more and more Americans identify as multiethnic or multiracial rather than as members of only one racial or ethnic group. It is now also increasingly recognized that age,

KEY TERMS

Adenocarcinoma—A general term for a type of cancer that originates in glandular tissue or behaves like glandular tissue. About 10% to 15% of cancers of the cervix are adenocarcinomas.

Cell line—A defined population of cells that can be maintained in culture for an extended period of time while retaining stable phenotypes and functions. Cell lines can be either finite (lasting for a limited period of time due to cellular senescence) or immortal (able to divide and reproduce indefinitely in a suitable culture medium as a result of mutations).

Cellular senescence—The point at which cell division stops in an average cell, usually around 50 successive divisions. This stopping point is called the Hayflick limit.

Common Rule—A federal policy for the protection of human research subjects in any study funded by the U.S. government; it was first defined in 1981 and amended in 2018. Formally stated in the Code of Federal Regulations, Title 45, Part 46, the Common Rule requires informed consent from all research subjects and the oversight of every study by an institutional review board (IRB).

Cytogenetics—The branch of genetics that studies the components of a cell associated with heredity, particularly the chromosomes.

DNA fingerprinting—A laboratory technique used to identify individuals by extracting and identifying base-pair patterns in a person's DNA. Originally developed to solve crimes or identify human remains, DNA fingerprinting has been used to detect cross-contamination in cell lines since the early 1990s.

Ethics—The branch of philosophy dealing with questions of good and evil, and with moral duties and obligations in human society.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Giemsa stain—A nucleic acid stain used to band chromosomes and to make a karyogram or map of

chromosomes. The stain is named for Gustav Giemsa (1867–1948), the German pharmacist and bacteriologist who devised the stain in 1904.

Haploid—Referring to cells that have only one chromosome of each type, and therefore have only one complete set of genes.

Hayflick limit—The number of times (usually around 50) that a normal differentiated human cell will divide before its telomeres shorten to a critical length and cell division stops. The limit is named for Leonard Hayflick, an American professor of anatomy who first described it in 1961.

Informed consent—The process in which health-care professionals explain the purpose, risks, benefits, and alternatives of a proposed test or treatment to a patient, and make sure that the patient understands the explanation.

Karyotype—The complete set of chromosomes in a species or individual organism. The term can also refer to the laboratory technique used to produce an image of an individual's chromosomes.

Phenotype—The set of observable characteristics or traits of an organism. It includes physical form and structure, development, metabolic processes, movement, and behavior.

Reproducibility—A major principle of the scientific method, used to confirm the validity of a new discovery by repeating the research that produced it.

Roller-tube technique—A technique used in tissue culture in which test tubes containing tissue or cell samples are held in a wheel-shaped instrument at a 15° angle from the horizontal, and the wheel is rotated vertically every 2 minutes. George Gey developed this technique in 1933.

Telomere—A region of repeated DNA sequences at each end of a chromosome that serves to stabilize the chromosome. Telomeres are progressively shortened each time the cell divides until cell division stops, usually around 50 divisions. HeLa cells are distinctive in that their telomeres are copied repeatedly during cell division, so that they are never shortened.

geographic location, and economic status are also important determinants of a person's access to health care alongside race or ethnicity.

Named in Lacks' honor, the Henrietta Lacks Enhancing Cancer Research Act of 2019 was passed by both houses of Congress in December 2020 and signed into

law as Public Law 116-291 by the President on January 5, 2021. The Act directs the Government Accountability Office to examine barriers to participation in clinical cancer trials by underrepresented groups—which the Act defines as “racial and ethnic minorities and older, rural, and lower-income individuals.” The Act notes that as of

QUESTIONS TO ASK YOUR DOCTOR

- Did you learn about the use of HeLa cells in research when you were in medical school?
- If so, were you aware of the controversies that had developed around the cells?
- In your opinion, why has research funding and the commercialization of biospecimens increased so dramatically since the 1950s?
- What do you think can be done at present to improve health care for underserved patient groups?

2021, about 1 in every 5 clinical trials for cancer therapy fail because of inadequate subject enrollment. It would be a fitting tribute to Henrietta Lacks if her life as well as her cell line led a new generation of clinical trial participants and scientists to a cure for a disease that had so few treatments in 1951.

Hemihypertrophy (Hemihyperplasia)

Definition

Hemihypertrophy, more correctly termed hemihyperplasia, is defined as the enlargement of one side of the body or part of the body.

Description

Hemihypertrophy is characterized by unequal (asymmetric) growth of the cranium, face, trunk, limbs, and/or digits. Hemihypertrophy can be an isolated finding, or it can be associated with certain malformation syndromes. Isolated hemihypertrophy refers to hemihypertrophy for which no cause can be found. The degree of asymmetry is variable, and very mild cases can go undiagnosed. There are three categories of hemihypertrophy, depending on the body parts involved. The size difference can involve only a specific part of the body such as a finger (called simple hemihypertrophy) or an entire half of the body (called total or complex hemihypertrophy). It usually involves only one side of the body, but it can involve both sides (called crossed). There is also hemifacial hyperplasia, which involves one side of the face. Usually multiple organ systems are involved (i.e., the skin, vascular system, internal organs, or bones). In complex hemihypertrophy, the right side is more often involved than the left.

Hemihypertrophy may involve not only the part of the body that is visible but also the underlying internal organs. Enlargement of one kidney, adrenal gland, testis, or ovary has been reported. The enlarged area usually also has thickened skin, more sebaceous (sweat) glands, and more hair. It may have pigmentary abnormalities, and the bones may be larger or may be deformed. In persons with facial involvement, the asymmetry can include the cheek, lip, nose, ear, eye, tongue, jaw, roof of the mouth, or teeth.

The nervous system may also be affected, causing unilateral nerve enlargement or sciatic nerve inflammation. Occasionally, a part of the brain is affected, causing intellectual disability (15% to 20% of cases). Many cases of hemihypertrophy have hamartomatous lesions (birthmarks that involve blood vessels) or abnormalities of the genito-urinary system.

As with other overgrowth syndromes, there is an increased risk for childhood cancers in people with isolated hemihypertrophy (about 6%), particularly cancers of the kidney (Wilms tumor, 3% of individuals), adrenals, and liver.

Genetic profile

The cause and exact mechanism of isolated hemihypertrophy is not known. The asymmetry occurs most likely as a result of an increase in the rate of cell growth or unregulated cell growth. Most cases of hemihypertrophy are not inherited, but there have been seven familial cases reported in which two or more persons were affected. These cases are not well documented, and it is possible that the families actually had another genetic syndrome. Males and females are equally affected with this condition.

It is clear that there is not a single gene responsible for hemihypertrophy, but the exact number of genes and their locations and functions are not known. It has been suggested that isolated hemihypertrophy may be related to another condition, called Beckwith-Wiedemann syndrome, a genetic overgrowth syndrome that can include both hemihypertrophy and Wilms tumor. Beckwith-Wiedemann syndrome has been associated with abnormalities on chromosome 11, which contains genes involved with growth, development, and cancer.

Good data do not exist for recurrence risk for siblings of patients or for children of affected persons. Case reports suggest a slightly increased risk for siblings and for offspring of affected mothers.

Demographics

Hemihypertrophy occurs in about 1 in 15,000 live births. Isolated hemihypertrophy occurs in about 1 in 86,000 live births. There are approximately 200 cases reported. Females and males are affected equally.

Signs and symptoms

Hemihypertrophy is usually recognized at birth by physical examination. It can become more serious over time, especially during puberty, when growth is more rapid. Very mild forms of this condition often go unnoticed and are very common.

Diagnosis

The diagnosis is made by clinical examination of body asymmetry. There are no laboratory tests available for this condition. Diagnostic imaging may show advanced bone age or larger bones in the hypertrophied limbs, supporting a diagnosis of hemihypertrophy, or characteristic bone changes supporting another diagnosis. Other genetic syndromes associated with asymmetry must be excluded, as must other causes of asymmetry, such as atrophy of one side of the body due to neurological disorder or skeletal abnormalities that cause asymmetric hand or limb enlargement.

The enlarged growth of only one side of the body is characteristic of hemihypertrophy. The asymmetric development may be isolated to one organ or limb or may occur to the entire body. (Gale)

Prenatal diagnosis is theoretically possible by ultrasound, provided that the difference in size is large enough to be detected or if an embryonic tumor is present, although a confirmed diagnosis is not possible until after birth.

Treatment and management

The treatment for hemihypertrophy is different for each individual and depends on the specific symptoms. If

leg-length differences are present, corrective shoes can increase the sole for the unaffected leg to prevent scoliosis and walking difficulties. Orthopedic devices such as braces or, more rarely, surgery to lengthen the normal leg may be indicated. Surgery to retard growth of the overgrown leg is controversial and not recommended. Surgery for congenital defects or laser surgery for birthmarks may be indicated. Plastic surgery may be considered to correct very discrepant facial features.

KEY TERMS

Hemi—One-sided.

Hypertrophy—Excessive development of an organ or part.

A protocol to screen for childhood cancers has been proposed, which includes abdominal ultrasound every three months until age six, every six months until puberty, and careful medical follow-up of patients into adulthood. Management of childhood hemihypertrophy includes occupational therapy and physical therapy as well. Surgical intervention is appropriate if cancers are detected. Monitoring of serum alpha fetoprotein levels may also be useful as a marker of hepatic tumors.

Appropriate special education services are necessary for those with intellectual disability. Counseling related to social stigmatism may be necessary if severe disfigurement is an issue.

Prognosis

Hemihypertrophy does not alter lifespan, although complications from associated abnormalities such as childhood cancer and intellectual disability can cause problems. Asymmetry of the limbs can interfere with their proper function and cause pain. Insecurities due to disfigurement are possible and can be addressed through support groups or therapy.

Hemochromatosis

Definition

Hemochromatosis is a blood disorder that results from an overload of iron in the body that can affect multiple organs, including the liver, pancreas, heart, thyroid, joints, skin, reproductive organs, and pituitary. Hemochromatosis is usually caused by a genetic condition that causes the body to retain excessive amounts of iron.

Description

Hemochromatosis is also known as iron overload, bronze diabetes, hereditary hemochromatosis, and familial hemochromatosis. It is most commonly caused by a

genetic condition that is also called primary or hereditary hemochromatosis. All other cases are called secondary hemochromatosis and are usually caused by either eating or drinking too much iron or having too many blood transfusions or by a condition where the body is producing too many red blood cells. Hereditary hemochromatosis causes increased absorption of intestinal iron, well beyond that needed to replace the body's loss of iron.

There are four types of hereditary hemochromatosis:

1. Type 1: Caused by mutations in the HFE gene.
2. Type 2a: Caused by mutations in the hemojuvelin gene and 2b caused by mutations in the hepcidin gene. Age of onset is usually 15 to 20 years. It is autosomal recessive, meaning that an affected individual has two pathogenic variants (mutations). They are both seen in Caucasians and non-Caucasians.
3. Type 3: Caused by mutations in the transferrin receptor-2 gene. It is autosomal recessive and seen in Caucasians and non-Caucasians. Age of onset is usually 30 to 40 years.
4. Type 4: Caused by mutations in the ferroportin gene. It is autosomal dominant, meaning that you need to only inherit one pathogenic variant of the ferroportin gene to get hemochromatosis. It is seen in Caucasians and non-Caucasians and has an age of onset of 10 to 80 years. HFE-related hemochromatosis is responsible for 90% of the cases of hereditary hemochromatosis and will be the focus of this entry.

Hemochromatosis causes excess iron storage in several organs of the body, including the liver, pancreas, endocrine glands, heart, skin, joints, and intestinal lining. The buildup of iron in these organs can lead to serious complications, including heart failure, liver cancer, and

cirrhosis of the liver. It is estimated that about 5% of cirrhosis cases are caused by hereditary hemochromatosis.

Genetic profile

Pathogenic variants (mutations) in the *HFE* gene causes HFE-related hemochromatosis. The *HFE* gene is located on chromosome 6. The *HFE* gene contains the instructions to produce the HFE protein, which appears to control the amount of iron taken up by the cells by interacting with the transferrin receptor. Transferrin binds and transports iron in the blood.

Hereditary hemochromatosis is an autosomal recessive condition, which means that an individual with hemochromatosis has pathogenic variants (mutations) in both of their *HFE* genes, which they inherited from their parents. Carriers have one *HFE* gene variant and one normal *HFE* gene. They do not typically have symptoms of hemochromatosis, as their normal gene is usually able to compensate for their gene with the pathogenic variant.

Children of two carrier parents have a 25% chance of inheriting two *HFE* gene variants and having hemochromatosis. Since hemochromatosis is so common in the United States, it is possible for both parents to have hemochromatosis or for one parent to be a carrier, and one parent to have hemochromatosis. If both parents have hemochromatosis, then all of their children will have it as well. If one is a carrier and the other has hemochromatosis, then there is a 50% chance that each child will have hemochromatosis. Because it is so common, there are families with multiple generations of family members with hemochromatosis, which is unusual for an autosomal recessive condition.

The likelihood that an individual will develop symptoms depends on which gene mutation he or she has as well as environmental factors. The age at which symptoms begin is variable, even within the same family. The two most common variants in the *HFE* gene are C282Y and H63D. Untreated individuals with two C282Y variations are more likely to have iron overload than are those with two H63D variants. However, some research suggests that H63D variants may be more associated with joint abnormalities and neurodegenerative diseases like dementia and ALS than C282Y variants.

Demographics

Hemochromatosis affects as many as 1.5 million persons in the United States. It is one of the most common genetic disorders in the United States. Between one in 200 and one in 400 people in the United States are affected

The hands of a healthy patient (far left and right) and a patient suffering from hemochromatosis, or iron overload (center). Hemochromatosis is the accumulation of iron in the body. Iron is stored in the liver, heart, and pancreas, and if untreated, the overabsorption can lead to organ failure. The most important causes are hereditary hemochromatosis (HHC), a genetic disorder, and transfusional iron overload, which can result from repeated blood transfusions. (Clinical Photography, Central Manchester University Hospitals NHS Foundation Trust, UK/Science Source)

with hereditary hemochromatosis. Approximately one in nine individuals (11%) is a carrier for hemochromatosis.

Men and women are equally affected by hemochromatosis, but women are diagnosed later in life because of blood loss from menstruation and childbirth. It most commonly appears in patients between the ages of 40 and 60, since it takes many years for the body to accumulate excessive iron. Symptoms in females usually occur after menopause.

Signs and symptoms

The symptoms of hemochromatosis include fatigue, weight loss, weakness, shortness of breath, heart palpitations, chronic abdominal pain, and impaired sexual performance. The patient may also show symptoms commonly connected with heart failure, diabetes, or cirrhosis of the liver. Changes in the pigment of the skin may appear, such as grayness in certain areas or a tanned or yellow (jaundice) appearance. The ages of onset and initial symptoms vary.

Diagnosis

The most common diagnostic methods for hemochromatosis are blood studies of iron, genetic testing, magnetic resonance imaging (MRI), and liver biopsy.

Blood studies of transferrin-iron saturation and ferritin concentration are often used to screen for iron overload. Ferritin is a protein that transports iron and liver enzymes. Additional studies are performed to confirm the diagnosis.

Studies that are used to confirm the diagnosis include additional iron studies and/or genetic testing. Genetic testing, which is a reliable method of diagnosis, became available in the late 1990s. Most individuals who are affected with hemochromatosis (90%) have two identifiable gene variants, so genetic testing will confirm the diagnosis. Genetic studies are also used to determine whether the affected person's family members are at risk for hemochromatosis. It is important to remember that not all people who inherit gene variants associated with hemochromatosis will have symptoms.

MRI scans and/or liver biopsy may be necessary to confirm the diagnosis. MRI studies of the liver, or other iron-absorbing organs, with quantitative assessment of iron concentration, may reveal abnormal iron deposits. For the liver biopsy, a thin needle is inserted into the liver while the patient is under local anesthesia. The needle will extract a small amount of liver tissue, which can be analyzed microscopically to measure its iron content and other signs of hemochromatosis.

KEY TERMS

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Cirrhosis—A chronic degenerative disease of the liver, in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

Diabetes mellitus—The clinical name for common diabetes. It is a chronic disease characterized by inadequate production or use of insulin.

Phlebotomy—The taking of blood from the body through an incision in the vein, usually in the treatment of disease.

Treatment and management

Patients who show signs of iron overload will often be treated with phlebotomy, a procedure that involves drawing blood from the patient, just like blood donation. Its purpose is to rid the body of excess iron. Patients may need these procedures once or twice per week for a year or more. Less-frequent phlebotomy may be continued in subsequent years to keep excess iron from accumulating. Patients who cannot tolerate phlebotomy can be treated with iron-chelating drugs like Desferal (desferrioxamine). Iron-chelators help the body excrete iron through urine or feces. Complications from hemochromatosis, such as cirrhosis or diabetes, may also require treatment.

Diet restrictions may help lower the amount of iron in the body, but they do not prevent or treat hemochromatosis. Individuals who have symptoms or who have variants in both copies of their *HFE* gene may reduce iron intake by avoiding iron and mineral supplements, excess vitamin C, and uncooked seafood. If a patient is symptomatic, he or she may be advised to abstain from drinking alcohol.

New treatments for hemochromatosis are being developed. For example, a drug called ebselen is being developed to prevent heart failure in hemochromatosis patients. Early research suggests that this drug may block the channels that allow iron to enter the heart. This, in turn, could help prevent heart failure.

Prognosis

With early detection and treatment, the prognosis is usually good. Most symptoms are prevented if iron levels

are kept within the normal range. This is easier if the diagnosis is made before an individual is symptomatic. If a patient is symptomatic but treated successfully before he or she develops liver cirrhosis, the patient's life expectancy is near normal. However, if left untreated, complications may arise that can be fatal. These include liver cancer, liver cirrhosis, diabetes mellitus, congestive heart failure, and difficulty depleting iron overload through phlebotomy. Liver biopsy can be helpful in determining prognosis of more severely affected individuals. Genetic testing may also help assess prognosis. Men are two times more likely than women to develop severe complications, since women have natural phlebotomy through menstruation.

Prevention

Screening for hemochromatosis can be cost-effective, especially for those of European ancestry. Relatives of patients with hemochromatosis—including children, siblings, and parents—should be tested. If genetic testing has not been done in the family, then the best testing method may be iron and ferritin studies. If the affected family member's diagnosis has been confirmed by genetic testing, then genetic testing of at-risk relatives would be recommended. Relatives who have hemochromatosis, but do not yet have symptoms, can reduce their risks by reducing their iron intake and beginning phlebotomy.

Population screening for hereditary hemochromatosis is widely debated. Many doctors and scientists want population screening because hemochromatosis is easily and cheaply treated, and quite common. Arguments against screening are that it may pick up individuals who will never have symptoms and may result in health and life insurance discrimination. The publicity around screening has been beneficial as it has increased awareness and testing for hemochromatosis in at-risk individuals.

Hemolytic-uremic syndrome

Definition

Hemolytic-uremic syndrome (HUS) is a syndrome defined by the presence of acute hemolytic anemia (low red blood cell count caused by the breakup of red cells within the bloodstream by a person's own immune system), thrombocytopenia (a low number of platelets), and kidney failure. Having these three symptoms all at once

can be caused by a number of problems—infections, genes, or a still-unknown cause.

Description

About 90% of HUS cases occur in children less than five years of age. In most cases, there is an early phase of diarrhea, followed by the lowered blood counts and the renal failure. Most patients get better after HUS, a few die during the worst stage of the illness, others go on to have life-long kidney disease, and some will progress to having a form of HUS that comes and goes over the rest of their lives. Which patients will have which outcome is not known during the illness.

Many infectious organisms have been thought to play a role as things that may cause HUS outbreaks, such as one *E. coli* serotype and one *Shigella dysenteriae* serotype. About 40% of patients who ingest *E. coli* 0157:H7 (the implicated serotype) will go on to get some form of diarrhea. Of those that develop diarrhea, about 5% will progress to some form of HUS (ranging in strength from mild to fatal). The bacteria linked to HUS have been shown to produce a toxin that gets released into the bloodstream after the organisms invade the colon's mucosal lining. The toxin, once inside of cells, disrupts protein synthesis. The spreading of organisms that make toxins tends to occur through food products.

Many outbreaks of HUS in the United States have occurred over the last several decades. These outbreaks have been linked to various food sources such as hamburger meat that is not cooked enough, apple juice and apple cider that has not been pasteurized, water, fruits, vegetables, and unpasteurized milk. Hamburger meat is the most common way that *E. coli* spreads. This bacterium is part of the normal flora of cow intestines, and it is thought that it gets into the meat during the process of killing and cutting up the cow. When this beef is then not cooked enough to kill the organism, it is able to travel into the human GI (gastro-intestinal) system with ease. The spreading of this disease can also occur with person-to-person contact through a fecal–oral route. Support for this theory includes data from daycare centers that had outbreaks of HUS.

About 10% of cases in children and 50% of cases in adults are a type of HUS that occurs without diarrhea. Of these cases, some can be linked with other infections, but other cases have no clear cause. Out of these unclear cases, some are a form of HUS that runs in families. There have been many research studies into families that have many members who have a form of HUS that keeps coming back over the patient's lifetime. Genetic tests of these families have found what may be a gene that can cause some cases of HUS.

KEY TERMS

Alternate complement pathway—A cascade of enzymatic reactions that produce antibacterial proteins. This pathway helps to ward off infections.

Idiopathic—Of unknown origin.

Serotype—One form of a bacteria that has unique surface proteins. Each serotype causes a unique antibody response from a person's immune system.

Patients with HUS all show signs of making thrombi (blood clots) in small vessels. These thrombi form in kidney blood vessels as well as small arteries all over the body. Thus, clots can cause infarcts (starvation and death) of kidney tissue, brain tissue, the bowel, and other organs.

Genetic profile

While most families have a form of HUS that passes on the disease in an autosomal recessive pathway, there have been some families with signs of autosomal dominant transmission. Genetic tests have found that a region on chromosome 1q can play a role in the forms of HUS that run in families. The gene for factor H (a protein regulator of the alternate complement pathway) is the leading gene candidate. Molecular proof linking factor H to cases of HUS that occur without diarrhea was first produced in 1998. Since then, screening of patients and families of patients with HUS not linked to a preceding episode of diarrhea have found a subset of patients who have mutated copies of the factor H gene.

Tests that look at different families with an inherited form of HUS have shown that there are many different point mutations within the factor H gene. All of these mutations led to some reduced level of factor H. With this lower level, many researchers have noticed that patients also have reduced levels of a protein called C3. This protein is part of the complement cascade that is supposed to attack bacteria within the body. Patients with low levels of C3 may be at more risk of having very bad problems arise from infections than patients with normal immune systems. Also, the familial form of HUS is most likely a multifactorial disease (i.e., no one gene mutation causes it by itself) that occurs in certain patients who are predisposed to the disorder.

Demographics

The largest number of cases occurs in children between the ages of six months and five years of age. The mean age of children who get HUS is four. Within

the United States, this disease most often occurs in epidemics, versus an endemic form that is found in other parts of the world. For example, Argentina has a much higher incidence of HUS than the United States. Interestingly, the prevalence of *E. coli* that make the toxins that cause infections is greater in Argentina.

Signs and symptoms

The clinical history most often seen in patients with HUS is of a diarrheal illness that comes before the anemia and renal disease by five to seven days. Some children have symptoms other than diarrhea. These include belly pain, nausea, and throwing up.

When HUS occurs, patients can have many different types of symptoms. Patients tend to have pallor (pale skin), decreased urine output, and fatigue. Even though they tend to have low platelet (the cells that cause blood to clot) counts, they seldom have too much bleeding. About one-quarter of patients have neurologic signs and symptoms that present as seizures, drowsiness, coma, and personality changes. Most of the patients that have HUS with diarrhea also have hypertension (high blood pressure). Almost one-fifth of patients with HUS have some form of pancreatic problems that can lead to the body not making enough insulin and causing diabetes. In some cases, the diabetes may last for the rest of the patient's life.

Kidney problems vary from patient to patient in how severe they may be. Some patients only have lower urine output, but others progress to full kidney failure. In some patients who develop HUS without diarrhea, the onset of renal failure is more subtle such that they present with symptoms of volume overload (too much retained fluid).

Diagnosis

The diagnosis of HUS should be considered in patients who present with symptoms of anemia or renal failure who either give a history of diarrhea before it or have certain problems that show up in their lab tests. Patients will always have low red blood cell counts (anemia) with signs of the ongoing breakdown of red blood cells. On peripheral smear (blood looked at through a microscope), Burr cells can be seen. These are red blood cells with bumps sticking out of the surface of the cell. Schistocytes (pieces of red blood cells that have been destroyed) can be seen under a microscope, which provide clues of the ongoing breakdown of red blood cells (hemolysis).

Diagnosis of familial HUS depends on the presence of many cases within one family that are not linked to an outside epidemic. Often, the cases occur over a stretch of many years. As of yet, there is no genetic or lab test

QUESTIONS TO ASK YOUR DOCTOR

- At what age is hemolytic uremic syndrome most commonly diagnosed, and how is that diagnosis made?
- If one child in a family has been diagnosed with hemolytic uremic syndrome, what are the chances that a second child will have the same disorder?
- What kinds of medications and other procedures are recommended for the ongoing treatment of hemolytic uremic syndrome?
- What support groups and organizations are there for parents of a child with hemolytic uremic syndrome?

that can tell which people will get familial HUS. Prenatal testing is not yet available either.

Treatment and management

There is no certain treatment for patients with HUS other than supportive care. Many types of treatments have been tried in attempts to reduce the amount of clotting that occurs in small vessels, but with little or no success. Antibiotic treatment for children with diarrhea caused by *E. coli* tended to raise, instead of lower, the rate of transformation into HUS. Thus, antibiotics tend not to be used for children with diarrhea. They are of little benefit and may be harmful. Treatment of diarrhea in children should consist of supportive care with ample fluids in order to prevent dehydration.

Careful notice must be paid to fluid intake. It is very easy for kidney failure patients to build up too much volume and have problems with their electrolyte levels. Patients with really low red blood cell counts can be given blood transfusions. Those who get severe renal failure may need dialysis treatment to rid their blood of toxins that would have been cleared by the kidneys. These treatments apply to all forms of HUS including HUS with diarrhea, HUS without diarrhea, and familial HUS. In some patients with recurring familial disease, kidney transplants have been tried, but the disease did recur in many patients.

Prognosis

As many as 25% of children die during the acute phase of the illness or are left with chronic renal or brain damage. Most of the deaths during the acute phase occur

in children where organs other than the kidneys are also involved (i.e., brain thrombi formation). Long-term effects also include diabetes, rectal stricture (narrowing of the rectum caused by fibrous tissue formation), and neurologic deficits (related to strokes). Of children who have HUS with diarrhea (most of the cases), about 1% will have the illness return.

In adults, the death rate is much higher, at 15%–30%. Thirty percent of those who do not die from HUS will have chronic kidney damage, and 25% may go on to have the disease recur. This difference in age-related recurrence rates and outcomes may be due to the fact that a higher number of adults get the form of HUS that begins without diarrhea.

Hemophilia

Definition

Hemophilia is a genetic disorder—usually inherited—of the mechanism of blood clotting. Depending on the degree of the disorder present in an individual, excess bleeding may occur only after specific, predictable events (such as surgery, dental procedures, or injury) or occur spontaneously, with no known initiating event.

Description

The normal mechanism for blood clotting is a complex series of events involving the interaction of the injured blood vessel, blood cells (called platelets), and over 20 different proteins that circulate in the blood.

Frontal X-ray showing the damaged knee joints of a hemophiliac. While hemophilia is often associated with external bleeding, it can also result in internal bleeding, which can damage and weaken the joints. (Mike Devlin/ Science Source)

When a blood vessel is injured in a way that causes bleeding, platelets collect over the injured area and form a temporary plug to prevent further bleeding. This temporary plug, however, is too disorganized to serve as a long-term solution, so a series of chemical events occur, resulting in the formation of a more reliable plug. The final plug involves tightly woven fibers of a material called fibrin. The production of fibrin requires the interaction of several chemicals, in particular a series of proteins called clotting factors. At least 13 different clotting factors have been identified.

The clotting cascade, as it is usually called, is the series of events required to form the final fibrin clot. The cascade uses a technique called amplification to rapidly produce the proper-sized fibrin clot from the small number of molecules initially activated by the injury.

In hemophilia, certain clotting factors are either decreased in quantity, absent, or improperly formed. Because the clotting cascade uses amplification to rapidly plug up a bleeding area, absence or inactivity of just one clotting factor can greatly increase bleeding time.

Hemophilia A is the most common type of bleeding disorder and involves decreased activity of factor VIII due to IgG antibodies attaching themselves to the domains of the factor that give it its function, therefore decreasing or obliterating its function. There are three levels of factor VIII deficiency: severe, moderate, and mild. This classification is based on the percentage of normal factor VIII activity present:

- Individuals with less than 1% of normal factor VIII activity level have severe hemophilia. Half of all people

with hemophilia A fall into this category. Such individuals frequently experience spontaneous bleeding, most frequently into their joints, skin, and muscles. Surgery or trauma can result in life-threatening hemorrhage and must be carefully managed.

- Individuals with 1%–5% of normal factor VIII activity level have moderate hemophilia and are at risk for heavy bleeding after seemingly minor traumatic injury.
- Individuals with 5%–40% of normal factor VIII activity level have mild hemophilia and must prepare carefully for any surgery or dental procedures.

Individuals with hemophilia B have symptoms very similar to those of hemophilia A, but the deficient factor is factor IX. This type of hemophilia is also known as Christmas disease.

Hemophilia C is very rare and much milder than hemophilia A or B; it involves factor XI.

Genetic profile

Hemophilia A and B are both caused by a genetic defect present on the X chromosome. (Hemophilia C is inherited in a different fashion.) About 70% of all people with hemophilia A or B inherited the disease. The other 30% develop the disorder from a spontaneous genetic mutation.

The following concepts are important to understanding the inheritance of these diseases. All humans have two chromosomes determining their gender: females have XX, and males have XY. Because the trait is carried only on the X chromosome, it is called “sex-linked.” The chromosome’s flawed unit is referred to as the gene.

Both factors VIII and IX are produced by a genetic defect of the X chromosome, so hemophilia A and B are both sex-linked diseases. Because a female child always receives two X chromosomes, she nearly always will receive at least one normal X chromosome. Therefore, even if she receives one flawed X chromosome, she is still capable of producing a sufficient quantity of factors VIII and IX to avoid the symptoms of hemophilia. Such a person who has one flawed chromosome but does not actually have the disease is called a carrier. She carries the flaw that causes hemophilia and can pass it on to her offspring. If, however, she has a son who receives her flawed X chromosome, he will be unable to produce the right quantity of factors VIII or IX, and he will suffer some degree of hemophilia. (Males inherit one X and one Y chromosome and, therefore, have only one X chromosome.)

In rare cases, a hemophiliac father and a carrier mother can pass on the right combination of parental chromosomes to result in a hemophiliac female child.

Hemophilia: pedigree analysis chart. (Gale)

This situation, however, is rare. The vast majority of people with either hemophilia A or B are male.

About 30% of all people with hemophilia A or B are the first member of their family to ever have the disease. These individuals have had the unfortunate occurrence of a spontaneous mutation, meaning that in their early development, some random genetic accident befell their X chromosome, resulting in the defect causing hemophilia A or B. Once such a spontaneous genetic mutation takes place, offspring of the affected person can inherit the newly created, flawed chromosome.

Demographics

Hemophilia affects all races and populations equally. As of 2015, there was an estimated worldwide rate of 3–20 cases per 100,000 people. Also, as of 2015, hemophilia was the most common coagulation factor deficiency and also had the highest associated treatment cost for a disorder.

Signs and symptoms

In the case of severe hemophilia, the first bleeding event usually occurs prior to 18 months of age. In some babies, hemophilia is suspected immediately, when a routine circumcision (removal of the foreskin of the penis) results in unusually heavy bleeding. Toddlers are at particular risk because they fall frequently and may bleed into the soft tissue of their arms and legs. These small bleeds result in bruising and noticeable lumps but don't usually need treatment. As a child becomes more active,

bleeding may occur into the muscles, a much more painful and debilitating problem. These muscle bleeds result in pain and pressure on the nerves in the area of the bleed. Damage to nerves can cause numbness and decreased ability to use the injured limb.

Some of the most problematic and frequent bleeds occur into the joints, particularly into the knees and elbows. Repeated bleeding into joints can result in scarring within the joints and permanent deformities. Individuals may develop arthritis in joints that have suffered continued irritation from the presence of blood. Mouth injuries can result in compression of the airway, and, therefore, can be life threatening. A blow to the head, which might be insignificant in a normal individual, can result in bleeding into the skull and brain. Because the skull has no room for expansion, the hemophiliac individual is at risk for brain damage due to blood taking up space and exerting pressure on the delicate brain tissue.

People with hemophilia are at very high risk of hemorrhage (severe, heavy, uncontrollable bleeding) from injuries such as motor vehicle accidents and also from surgery.

Some other rare clotting disorders such as Von Willebrand disease present similar symptoms but are not usually called hemophilia.

Diagnosis

Various tests are available to measure, under very carefully controlled conditions, the length of time it takes

Hemophilia: pedigree analysis chart. (Gale)

to produce certain components of the final fibrin clot. Tests called assays can determine the percentage of factors VIII and IX present compared to normal percentages. This information can help in demonstrating the type of hemophilia present, as well as the severity.

Individuals with a family history of hemophilia may benefit from genetic counseling before deciding to have a baby. Families with a positive history of hemophilia can have tests done during a pregnancy to determine whether the fetus is a hemophiliac. The test, called chorionic villus sampling, examines proteins for the defects that lead to hemophilia. This test, which is associated with a 1% risk of miscarriage, can be performed at 10–12 weeks. Another test, amniocentesis, examines the DNA of fetal cells shed into the amniotic fluid for genetic mutations. Amniocentesis, which is associated with a 1 in 200 risk of miscarriage, is performed at 16–18 weeks gestation.

Treatment and management

The most important thing that individuals with hemophilia can do to prevent complications of the disorder is to avoid injury. Those individuals who require dental work or any surgery may need to be pretreated with an infusion of factor VIII to avoid hemorrhage. Also, hemophiliacs should be vaccinated against hepatitis. Medications or drugs that promote thinning of the blood or bleeding, such as aspirin, should be avoided.

Various types of factors VIII and IX are available to replace a patient's missing factors. These are administered intravenously (directly into the patient's veins by needle). These factor preparations may be obtained from a single donor, by pooling the donations of as many as thousands of donors or by laboratory creation through highly advanced genetic techniques.

The frequency of treatment with factors depends on the severity of the individual patient's disease. Patients with relatively mild disease require treatment only in the event of injury or to prepare for scheduled surgical or dental procedures. Patients with more severe disease require regular treatment to avoid spontaneous bleeding. If bleeding does occur, antihemorrhagic drugs are usually administered.

While appropriate treatment of hemophilia can both decrease suffering and be life-saving, complications associated with treatment can be quite serious. About 20% of all patients with hemophilia A begin to produce chemicals in their bodies that rapidly destroy infused factor VIII. The presence of such a chemical may greatly hamper efforts to prevent or stop a major hemorrhage.

Individuals who receive factor prepared from pooled donor blood are at risk for serious infections that may be passed through blood. Hepatitis, a severe and potentially fatal viral liver infection, may be contracted from pooled factor preparations. A good deal of concern has been raised about the possibility of hemophiliacs contracting a fatal slow virus infection of the brain (Creutzfeldt-Jakob disease) from blood products. Unfortunately, pooled factor preparations in the early 1980s were contaminated with human immunodeficiency virus (HIV), the virus that causes AIDS. A large number of hemophiliacs were infected with HIV, and some statistics show that HIV is still the leading cause of death among hemophiliacs. Careful methods of donor testing, as well as methods of inactivating viruses present in donated blood, have greatly lowered this risk.

New treatments currently being researched involve efforts to transfer new genes to hemophiliacs. These new genes would have the ability to produce the missing factors. As yet, these techniques are not being performed

KEY TERMS

Amplification—A process by which something is made larger. In clotting, only a very few chemicals are released by the initial injury; they result in a cascade of chemical reactions that produces increasingly larger quantities of different chemicals, resulting in an appropriately sized, strong fibrin clot.

Factors—Substances in the blood, such as proteins and minerals, that are necessary for clotting. Each clotting substance is designated with roman numerals I through XIII.

Fibrin—The final substance created through the clotting cascade, which provides a strong, reliable plug to prevent further bleeding from the initial injury.

Hemorrhage—Very severe, massive bleeding that is difficult to control. Hemorrhage can occur in hemophiliacs after what would be a relatively minor injury to a person with normal clotting factors.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease and can be transmitted to offspring.

Platelets—Small disc-shaped structures that circulate in the bloodstream and participate in blood clotting.

Trauma—Injury.

on humans, but there is a possibility that eventually this type of gene therapy will be available.

As of 2015, bypassing agents and other homeostatic therapies had also been studied for the treatment of hemophilia A. Although these are emerging treatment options that need more conclusive studies, there is already evidence of their efficacy for treating patients with severe hemophilia A.

Management of hemophilia may also include surveillance by diagnostic imaging to closely monitor any resulting bone and joint disease. Support from a physiotherapist may also be recommended for exercise supervision.

Prognosis

Prognosis is very difficult to generalize. Because there are so many variations in the severity of hemophilia,

QUESTIONS TO ASK YOUR DOCTOR

- Are there any activities or sports I should avoid?
- Which type of hemophilia do I have, and how severe is it?

and because much of what befalls a hemophiliac patient depends on issues such as physical activity level and accidental injuries, statistics on prognosis are not generally available.

Hepatocellular carcinoma

Definition

Hepatocellular carcinoma (HCC), or liver cancer, is a form of cancer with a high mortality rate. It is also called malignant hepatoma. Liver cancers in general can be

classified into two types. They are either primary, when the cancer starts in the liver itself; or metastatic, when the cancer has spread to the liver from some other part of the body.

Description

Primary liver cancer

Primary liver cancer is the sixth most commonly diagnosed cancer in the world. About 80% of all primary liver cancers are hepatocellular carcinomas. Primary liver cancer is, however, a relatively rare disease in the United States, representing about 2% of all malignancies. It is much more common in other parts of the world, representing from 10% to 50% of malignancies in Africa and parts of Asia.

In adults, most primary liver cancers belong to one of two types: hepatomas, or hepatocellular carcinomas, which start in the liver tissue itself; and cholangiomas, or cholangiocarcinomas, which are cancers that develop

in the bile ducts inside the liver. About 80% of primary liver cancers are hepatomas. The American Cancer Society estimated that in the United States, at least 42,230 new cases of liver and bile duct cancers would be diagnosed in the United States in 2021 (28,980 in men, and 12,340 in women), and roughly 30,230 deaths from these cancers in the same year. The rate of primary liver cancer has been slowly rising in North America since the 1980s.

There is one type of primary liver cancer that usually occurs in children younger than four years of age and between the ages of 12 and 15, called a hepatoblastoma. Unlike liver cancers in adults, hepatoblastomas have a good chance of being treated successfully. Approximately 70% of children with hepatoblastomas experience complete cures. If the tumor is detected early, the survival rate is over 90%.

Metastatic liver cancer

The second major category of liver cancer, metastatic liver cancer, is about 20 times as common in the United

Comparing the appearance of a healthy liver (left) with its appearance in cirrhosis and hepatocellular carcinoma (liver cancer). Cirrhosis is a consequence of chronic liver disease characterized by replacement of liver tissue with fibrosis, scar tissue, and regenerative nodules (lumps that occur as a result of damaged tissue being regenerated), leading to loss of liver function. Liver cancer is often secondary to cirrhosis. (Monica Schroeder/Science Source)

States as primary liver cancer. Because blood from all parts of the body must pass through the liver for filtration, cancer cells from other organs and tissues easily reach the liver, where they can lodge and grow into secondary tumors. Primary cancers in the colon, stomach, pancreas, rectum, esophagus, breast, lung, or skin are the most likely to spread (metastasize) to the liver. It is not unusual for the metastatic cancer in the liver to be the first noticeable sign of a cancer that started in another organ. After cirrhosis, metastatic liver cancer is the most common cause of fatal liver disease.

Genetic profile

Hepatocellular carcinoma has occasionally been reported to occur in familial clusters. It appears that first-degree relatives (siblings, children, or parents) of people with primary liver cancer are 2.4 times more likely to develop liver cancer themselves. This finding indicates a small overall genetic component; however, specific disease genes that are directly causative of HCC had not been identified as of 2021.

Certain genetic diseases are, however, associated with a higher risk of liver cancers. These include hereditary hemochromatosis, an iron-storage disease most often caused by mutations in the *HFE* gene on the short arm of chromosome 6 at 6p22.2; alpha-1 antitrypsin deficiency, a disorder caused by mutations in the *SERPINA1* gene on the long arm of chromosome 14 at 14q32.13 that leads to deposits of an abnormal protein in liver cells as well as emphysema and other respiratory symptoms; glycogen storage diseases, classified into 11 different genetic types as of 2015; tyrosinemia, a group of three genetic disorders characterized by the body's inability to metabolize the amino acid tyrosine; Fanconi anemia, a clinically heterogeneous disorder associated with mutations in the *FANCA* gene on the long arm of chromosome 16 at 16q24.3; and Wilson disease, a disorder in which copper accumulates in body tissues. Wilson disease is caused by mutations in the *ATP7B* gene on the long arm of chromosome 13 at 13q14.3.

A 2021 study sought to determine the role of microRNA-145-5p and AFR6 on how HCC cancer cells

migrate, invade, and metastasize. Low expression levels of miR-14505p were found to be linked with poor prognosis in patients with HCC and with some features of metastatic tumors. Further study could provide an opportunity for better understanding of HCC metastasis and lead to new therapy options.

Although much work needs to be done before research will lead to more effective therapies for HCC, molecular profiling of liver tumors is being done in order to develop targeted therapies for the disease. As of spring 2021, genomic sequencing has found that some gene mutations perform as drivers of HCC, although further study was needed. Among these are *TP53*, a tumor suppressor gene, along with *TERT*, *CTNNB1*, *ARID1A*, and *ARID2*.

Demographics

Hepatocellular carcinoma is the sixth most common cancer of men and the eleventh most common cancer of women worldwide, affecting 250,000 to one million individuals annually. HCC is responsible for about 782,000 deaths each year worldwide. Although liver cancer is becoming more common in the United States, it is 10

times more common in Africa and Asia, where it is the most common type of cancer. In China, 90% of cases of HCC are caused by hepatitis B infection; in Japan, 90% of cases are associated with hepatitis C. Liver cancer affects men more often than women; men in the United States have a lifetime risk of one in 81 of developing primary liver cancer, while women have a lifetime risk of one in 196.

Like most cancers, liver cancer in the countries is more common in older individuals; the average age at diagnosis is 63. Only 2% of patients with HCC in North America are younger than 35. In Africa, however, the average age of patients with HCC is about 30, largely because of the continent's high rates of hepatitis infection.

Risk factors for primary liver cancer

The exact cause of primary liver cancer is still unknown. In adults, however, certain factors are known to place some individuals at higher risk of developing liver cancer, including:

- Exposure to hepatitis B (HBV) or hepatitis C (HCV) viruses. In Africa and most of Asia, exposure to hepatitis B is an important factor; in Japan and some Western countries, exposure to hepatitis C is connected with a higher risk of developing liver cancer. In the United States, nearly 25% of patients with liver cancer show evidence of HBV infection. Hepatitis is commonly found among intravenous drug abusers.
- Exposure to substances in the environment that are known to cause cancer (carcinogens). These include a substance produced by a mold that grows on rice and peanuts (aflatoxin); thorium dioxide, which was used at one time as a contrast dye for x-rays of the liver; and vinyl chloride, a now strictly regulated chemical used in manufacturing plastics.
- Cirrhosis. Hepatomas appear to be a frequent complication of cirrhosis of the liver. Between 30% and 70% of hepatoma patients also have cirrhosis. It is estimated that a patient with cirrhosis has 40 times the chance of developing HCC as a person with a healthy liver.
- Obesity and type 2 diabetes. Both conditions increase the risk of cirrhosis of the liver.
- History of smoking. People who have quit smoking are at lower risk of HCC than those who continue to smoke, but both groups are at higher risk of HCC than people who have never smoked.
- Use of anabolic steroids (male hormones) for medical reasons or strength enhancement. Cortisone-like steroids do not appear to increase risk for liver cancer.

- Hereditary hemochromatosis. Hemochromatosis is a disorder characterized by abnormally high levels of iron storage in the body. It often develops into cirrhosis.
- Geographic location. Liver cancer is ten times more common in Asia and Africa than in the United States.
- Ethnicity. In North America, HCC is most common in Asian Americans and Pacific Islanders, followed by Native Americans, Hispanics, African Americans, and Caucasians.
- Male sex. The male/female ratio for hepatoma is three to one as of 2015.

Signs and symptoms

The early symptoms of primary as well as metastatic liver cancer are often vague and not unique to liver disorders. The long lag time between the beginning of the tumor's growth and signs of illness is the major reason why the disease has such a high mortality rate. At the time of diagnosis, patients are often tired, complaining of fever, abdominal pain, unintended weight loss, and loss of appetite. They may look emaciated and generally ill.

As the tumor grows bigger, it stretches the membrane surrounding the liver (the capsule), causing pain in the upper abdomen on the right side. The pain may extend into the back and shoulder. Some patients develop a collection of fluid known as ascites in the abdominal cavity. Others may show signs of bleeding into the digestive tract, including blood in the stool. In addition, the tumor may block the ducts of the liver or the gall bladder, leading to jaundice. In patients with jaundice, the whites of the eyes and the skin may turn yellow, and the urine becomes dark-colored.

Diagnosis

Physical examination

If the doctor suspects a diagnosis of liver cancer, he or she will check the patient's history for risk factors and will pay close attention to the condition of the patient's abdomen during the physical examination. Masses or lumps in the liver and ascites can often be felt while the patient is lying flat on the examination table. The liver is usually swollen and hard in patients with liver cancer; it may be sore when the doctor presses on it. In some cases, the patient's spleen is also enlarged (splenomegaly). The doctor may be able to hear an abnormal sound (bruit) or rubbing noise (friction rub) if he or she uses a stethoscope to listen to the blood vessels that lie near the liver. The noises are caused by the pressure of the tumor on the blood vessels.

Laboratory tests

Blood tests may be used to test liver function or to evaluate risk factors in the patient's history. Between 50% and 75% of primary liver cancer patients have abnormally high blood serum levels of a particular protein (alpha-fetoprotein, or AFP). The AFP test alone cannot be used to confirm a diagnosis of liver cancer, because cirrhosis or chronic hepatitis can also produce high alpha-fetoprotein levels. Tests for alkaline phosphatase, bilirubin, lactic dehydrogenase, and other chemicals indicate that the liver is not functioning normally. About 75% of patients with liver cancer show evidence of hepatitis infection. Again, however, abnormal liver function test results are not specific for liver cancer.

Blood tests also might reveal an important biomarker for HCC in patients who have hepatitis B. Values of serum Integrin beta-like 1 (ITGBL1) can indicate an early diagnosis of HCC associated with hepatitis B. This early diagnosis is important to reducing mortality from the disease in at-risk populations.

Imaging studies

Imaging studies are useful in locating specific areas of abnormal tissue in the liver. Liver tumors as small as an inch across can now be detected by ultrasound or computed tomography (CT) scan. Imaging studies, however, cannot tell the difference between a hepatoma and other abnormal masses or lumps of tissue (nodules) in the liver. A sample of liver tissue for biopsy is needed to make the definitive diagnosis of a primary liver cancer. CT or ultrasound can be used to guide the doctor in selecting the best location for obtaining the biopsy sample. Chest x-rays may be used to see whether the liver tumor is primary or has metastasized from a primary tumor in the lungs.

Liver biopsy

Liver biopsy is considered to provide the definite diagnosis of liver cancer. In about 70% of cases, the biopsy is positive for cancer. In most cases, there is little risk to the patient from the biopsy procedure. In about 0.4% of cases, the patient develops a fatal hemorrhage from the biopsy because some tumors are supplied with a large number of blood vessels and bleed very easily.

Laparoscopy

The doctor may also perform a laparoscopy to help in the diagnosis of liver cancer. A laparoscope is a small, tube-shaped instrument with a light at one end. The doctor makes a small cut in the patient's abdomen and inserts the laparoscope. A small piece of liver tissue is removed and examined under a microscope for the presence of cancer cells.

KEY TERMS

Ablation—A general term for medical techniques for destroying a cancer (or other unwanted tissue) without removing it.

Aflatoxin—A mycotoxin, produced by several species of *Aspergillus* fungi, that is a known carcinogen.

Ascites—An abnormal collection of fluid in the abdominal cavity. It is most often caused by cirrhosis, metastatic liver cancer, or other severe liver disease.

Carcinogen—Any substance or radioactive material that is directly implicated in causing cancer.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing them.

Cirrhosis—A condition of liver dysfunction resulting from long-term damage, most often caused by heavy alcohol consumption, hepatitis B or C infection, or non-alcoholic fatty liver disease.

Embolization—A technique for treating some types of bleeding disorders or cancer by blocking blood vessels.

Hemochromatosis—A condition in which iron accumulates in the body, as a result of either a

genetic mutation or frequent blood transfusions. It is also known as iron storage disease.

Hepatectomy—The medical term for surgical removal of the liver. A hepatectomy may be either partial or total.

Metastasis (plural: metastases)—The spreading of cancer from the original site to other locations in the body.

Primary tumor—The organ or tissue where a tumor began.

Protocol—A set of guidelines for medical tests or treatments.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Stage—The extent of a tumor's progress. Tests are done to determine whether a tumor is localized to an organ or whether it has spread to the lymph nodes and/or other organs. Treatment is determined by the stage of the cancer.

Tumor—An abnormal growth of cells. A tumor may be benign (noncancerous) or malignant (cancerous).

Treatment and management

Treatment of liver cancer is based on several factors, including the type of cancer (primary or metastatic); the stage (early or advanced); the location of other primary cancers or metastases in the patient's body; the patient's age; and other coexisting diseases, including cirrhosis. Treatment options include surgery, radiation, and chemotherapy. At times, two or all three of these may be used together. For many patients, treatment of liver cancer is primarily intended to relieve the pain caused by the cancer but cannot cure it.

Surgery

The goal of surgery is to remove the entire tumor, curing liver cancer. However, few liver cancers in adults can be cured by surgery, because they are usually too advanced by the time they are discovered. If the cancer is contained within one lobe of the liver, and if the patient does not have cirrhosis, jaundice, or ascites, surgery is the best treatment option. Patients who can have their entire tumor removed have the best chance of survival.

If the entire visible tumor can be removed, about 25% of patients will be cured. The operation that is

performed is called a partial hepatectomy, or partial removal of the liver. The surgeon will remove either an entire lobe of the liver (a lobectomy) or cut out the area around the tumor (a wedge resection).

Doctors may also offer tumor embolization or ablation. Embolization involves killing a tumor by blocking its blood supply. The newest form of embolization, called radioembolization, involves injecting small beads containing a radioactive isotope of yttrium into the hepatic artery. The beads both seal off the artery and release small amounts of radiation into the area of the tumor. Ablation is a method of destroying a tumor without removing it. One method of ablation, cryosurgery, involves freezing the tumor, thereby destroying it. In another method of ablation, ethanol ablation, doctors kill the tumor by injecting alcohol into it. A third method is called radiofrequency ablation, or RFA. In RFA, the tumor is destroyed by heat generated by high-frequency radio waves. Unlike some other therapies, RFA can be repeated several times if needed.

Chemotherapy

Chemotherapy involves using very strong drugs, taken by mouth or intravenously, to suppress or kill tumor

QUESTIONS TO ASK YOUR DOCTOR

- What stage is the cancer?
- Is my cancer related to a genetic disorder?
- What treatment(s) will you recommend?

cells. Chemotherapy also damages normal cells, leading to such side effects as hair loss, vomiting, mouth sores, loss of appetite, and fatigue.

Some patients with incurable metastatic cancer of the liver can have their lives prolonged for a few months by chemotherapy. If the tumor cannot be removed by surgery, a tube (catheter) can be placed in the main artery of the liver, and an implantable infusion pump can be installed (hepatic artery infusion, or HAI). The pump allows much higher concentrations of cancer drugs to be carried directly to the tumor.

Hepatocellular carcinoma is resistant to most drugs. Such drugs as capecitabine, gemcitabine, doxorubicin, and sorafenib are being used to treat this type of cancer. Systemic chemotherapy is used most often; however, in clinical trials as of 2015 it was not found effective in prolonging patients' lives.

Radiation therapy

Radiation therapy is the use of high-energy rays or x-rays to kill cancer cells or to shrink tumors. In liver cancer, radiation can give only brief relief from some of the symptoms, including pain. Liver cancers are not sensitive to levels of radiation considered safe for surrounding tissues. Radiation therapy has not been shown to prolong the life of a patient with liver cancer.

Liver transplantation

Removal of the entire liver (total hepatectomy) or liver transplantation is used only rarely in treating liver cancer, and then only for patients with early-stage HCC. On average, about 1,300 liver transplants are performed in the United States for people with liver cancer. Few patients are eligible for this procedure, however, either because the cancer has spread beyond the liver or because there are no suitable donors. Further research in the field of transplant immunology may make liver transplantation a possible treatment method for more patients in the future.

Targeted therapy

As researchers learn more about the genes associated with HCC, they can design targeted therapies. As of 2021, tyrosine kinase inhibitors were used to target some primary liver cancers. The inhibitors can get through a cancer cell membrane and block signals that make the cells grow and divide. Another targeted approach is tepotinib, a MET inhibitor for patients who have HCC and MET overexpression and have not responded to the drug Nexavar.

Prognosis

Liver cancer has a poor prognosis because it is often not diagnosed until it has metastasized. Another reason for the poor prognosis is that many patients with HCC also have cirrhosis or hepatitis, conditions that can be fatal in themselves. The overall five-year survival rate for patients with hepatomas was around 15% as of 2015. Many patients with primary liver cancer die within several months of diagnosis. Patients with liver cancers that metastasized from cancers in the colon live slightly longer than those whose cancers spread from cancers in the stomach or pancreas. There are no useful strategies at present for preventing metastatic cancers of the liver. Primary liver cancers, however, are 75% to 80% preventable. Current strategies focus on widespread vaccination for hepatitis B; early treatment of hereditary hemochromatosis; and screening of high-risk patients with AFP testing and ultrasound examinations.

Lifestyle factors that can be modified in order to prevent liver cancer include avoidance of exposure to toxic chemicals and foods harboring molds that produce aflatoxin. In the United States, laws protect workers from exposure to toxic chemicals. Changing grain-storage methods in other countries may reduce aflatoxin exposure. Avoidance of alcohol and drug abuse is also an important preventive measure. Alcohol abuse is responsible for 60% to 75% of cases of cirrhosis, which is a major risk factor for eventual development of primary liver cancer.

A vaccine for hepatitis B has been available since 1982. The National Cancer Institute (NCI) considers immunization with this vaccine to be one of the most important preventive measures a person can take to reduce the risk of HCC. Widespread immunization prevents infection, reducing a person's risk of liver cancer. Other protective measures against hepatitis include using protection during sex and not sharing needles. Scientists have found that interferon injections may lower the risk for someone with hepatitis C or cirrhosis to develop liver cancer.

Herceptin

Definition

Herceptin is a medicine that is used to slow or stop the growth of a cancerous tumor associated with the human epidermal growth factor receptor 2.

Purpose

Herceptin is used to treat cancer that has spread to other parts of the body in patients whose tumor cells produce an overabundance of a protein known as the human epidermal growth factor receptor 2 (HER2). Types of cancer currently treated by Herceptin include breast cancer and gastric cancer.

Description

Also known by its generic name, trastuzumab, Herceptin is an antineoplastic drug manufactured by Genentech, Inc. A monoclonal antibody, Herceptin works differently than chemotherapy or hormonal anticancer drugs. It targets cancer cells that make too much of the HER2 protein, which is found on the surface of the cancer cells and is thought to fuel cancer growth. Used only to treat cancers that make an overabundance of HER2 protein, Herceptin works by binding to the protein's particles and blocking its effect, thereby slowing down or stopping the cancer cell growth. The HER2 proteins with Herceptin are removed from the surface of the cell. When this happens, they cannot tell the cell to grow and divide.

In addition, Genentech, Inc., explains that there may be two other factors that account for Herceptin's effectiveness: Herceptin signals the immune system and works with chemotherapy. After Herceptin binds to the HER2 protein, the natural killer cells of the immune system are attracted to Herceptin. Herceptin, in turn, binds to the natural killer cells and determines which ones are abnormal and helps to kill them. When this occurs, chemotherapy may be enhanced. Although Herceptin and chemotherapy work differently, Genentech points out that when used together, "the two drugs can be synergistic. Treatment with Herceptin prevents DNA repair following the impact of DNA-damaging chemotherapy that stops the tumor cells from growing."

According to the National Cancer Institute, approximately 25%–30% of breast cancers make too much HER2 protein. These kinds of tumors tend to grow faster and are more likely to recur. The amount of HER2 that is present in a tumor is determined by a lab test, and a score from 0 (which is a negative score) to 3+ (which is a highly positive score) is assigned. Only patients with high scores are expected to benefit from Herceptin treatment.

Clinical use

Two groundbreaking clinical trials were conducted to test the safety and efficacy of Herceptin. One of them, conducted by Dr. Dennis Slamon and colleagues, produced data that led to Herceptin's approval by the U.S. Food and Drug Administration (FDA) in 1998. In 2001, the *New England Journal of Medicine* published the study results by Slamon and colleagues, which involved 234 randomly assigned patients who received chemotherapy alone and 235 patients who received chemotherapy plus Herceptin. All the patients in the study were diagnosed with metastatic breast cancer that overproduced HER2. Ultimately, Slamon and colleagues concluded that the addition of Herceptin to chemotherapy was associated with "a longer time to disease progression, a higher rate of response [to the treatment], longer survival, and a 20% reduction in the risk of death," as compared to treatment with chemotherapy alone. Specifically, for example, Herceptin combined with paclitaxel proved to be especially valuable; the overall response rate rose from 15% in women treated with paclitaxel to 38% in women treated with Herceptin and paclitaxel. All factors considered, Herceptin seems to increase the clinical benefits of first-line chemotherapy.

In another clinical trial, as explained by the National Cancer Institute, "Women were given only Herceptin. In 14% of these women, the tumor got smaller or disappeared." Therefore, in September 1998 the FDA announced its approval of Herceptin for the treatment of metastatic breast cancer. Use of the medicine has since been successful. Herceptin was specifically approved in combination with paclitaxel as therapy for HER2 breast cancer. It is also used alone as a therapy after other therapies have failed. Used by itself or with chemotherapy, Herceptin is the first FDA-approved therapy that targets a particular genetic defect known to play a role in cancer development.

Herceptin has also been used in the treatment of gastric cancer. Although it has been successful in treating gastric cancer, Herceptin-resistant gastric cancer and Herceptin-resistant breast cancer has been noted.

Other possible uses for Herceptin

Herceptin is also being studied as an adjuvant therapy for the treatment of nonmetastatic breast cancer that has spread to the lymph nodes but not anywhere else.

Herceptin may also be useful in fighting cancers of the lung, colon, prostate, and bladder in patients whose tumors have an overabundance of HER2. Several studies are underway to test the effectiveness of Herceptin with and without other anticancer drugs.

Recommended dosage

Herceptin is administered intravenously on a weekly basis in a hospital or clinic setting. Based on the patient's body weight, the typical dosage is 0.9 to 3.6 mg per pound.

Precautions

It is important to have periodic blood tests while taking Herceptin because it can cause anemia and a low white blood cell count in many patients. Monitoring the cardiac health of patients taking Herceptin is imperative because using it can lead to congestive heart failure. Therefore, some patients may not be able to take Herceptin.

It is not known whether Herceptin is safe to take while a patient is pregnant. Nonetheless, patients should avoid becoming pregnant while they are taking Herceptin. Pregnant patients should talk with their physicians regarding any possible risks to the fetus. Mothers should not breastfeed their babies while they are being treated with Herceptin because it does pass to the breast milk. In fact, mothers should not breastfeed for at least six months after being treated with Herceptin.

Side effects

The two most serious side effects associated with the use of Herceptin are cardiac and lung related. Damage to the heart muscle (which can cause heart failure) and lung complications (which can cause serious breathing problems) can occur. In both cases, immediate medical attention is required. Whether during or after treatment, patients experiencing difficulty breathing or any of the signs associated with heart failure, such as shortness of breath, a fast heartbeat, or swelling in the feet or legs, should contact their physicians without delay. Cardiac side effects are more frequently experienced by elderly patients. In clinical trials, it was found that patients receiving Herceptin with anthracycline chemotherapy were more likely to experience cardiac dysfunction than those who did not receive anthracyclines. Patients treated with Herceptin must be monitored carefully and screened prior to their treatment for any lung or heart problems. It is sometimes necessary to discontinue treatment with Herceptin.

The National Cancer Institute cautions patients that Herceptin can cause severe allergic reactions, such as low blood pressure, shortness of breath, rashes, and wheezing. These reactions are usually more common in patients who already have lung disease.

Fever and chills are common during the first infusion and occur less frequently thereafter. Throughout Herceptin

treatment it is not uncommon for patients to experience nausea, vomiting, diarrhea, dizziness, sleeplessness, appetite loss, cough, abdominal and back pain, headache, and sore throat. Depression, tingling in the hands or feet, fluid retention, sinus irritation, and flu-like symptoms are less commonly reported. Uncommon side effects are acne, cold sores, and urinary infection, as well as pain in the joints, bones, or nerves. As reminded by the National Cancer Institute, it is important to note that patients being treated with Herceptin alone in comparison to patients being treated with Herceptin and chemotherapy may have different side effects. For example, when Herceptin is used in combination with chemotherapy, patients are more likely to experience anemia leukopenia, diarrhea, and infection. Therefore, blood tests may be required more frequently for patients being treated with both Herceptin and chemotherapy. Rare side effects can develop in any part of the body, regardless of whether a patient is being treated with Herceptin only or in combination with chemotherapy. Patients should inform their physicians when they experience any side effects, regardless of whether the side effects are mild or severe. Some side effects, such as pain, can be managed medically.

Whether in the early or advanced stages, cancer itself can cause pain. In fact, numerous studies have validated that patients with advanced cancer are likely to have a number of symptoms in addition to pain, such as insomnia, depression, and fatigue. Therefore, it is valuable, if possible, to determine whether the source of the pain is the drug therapy or the cancer itself. Once the source of the pain is determined, it is easier to decide what the next course of action should be. Patients should be their own healthcare advocates and work as closely as possible with their physicians regarding treatment strategies for adverse side effects and cancer-related pain. Patients should talk with their physicians about a variety of treatment modalities that range from conventional options to alternative therapies, such as acupuncture.

Pain intensity should also be considered when developing a treatment plan to cope with unpleasant side effects. Certain pain measurement tools, such as the Visual Analogue Pain Scale (VAPS) and the McGill Pain Questionnaire, are commonly used by physicians to assess pain intensity. Patients having difficulty coping with the pain associated with cancer and cancer drugs might find it helpful to be referred to a physician who specializes in pain management or a pain clinic. Physicians specializing in the treatment of pain come from a variety of medical backgrounds, such as anesthesiology, obstetrics and gynecology, neurology, and surgery. Because of the complicated nature of cancer and cancer-related pain, ideally a pain management team should be formed that works with the patient's primary care physician, oncologist, and radiologist to provide comprehensive care to the patient.

Advances in cancer treatment lengthen survival among cancer patients. It is important for cancer patients to understand that they are not alone. Support groups exist to help patients cope not only with the physical aspects of having cancer but also with the psychological ones. In addition, the positive support (both emotional and otherwise) provided by caregivers can help to improve a patient's quality of life.

Interactions

There are no known food interactions with Herceptin. However, as mentioned earlier, cardiac dysfunction is especially high in patients who received Herceptin in combination with anthracycline chemotherapy. Patients should discuss any medications (over-the-counter, herbal, and prescription) that they are taking with their physician so that an assessment can be made regarding the risk of interactions.

There are, in fact, a multitude of precautions and interactions related to chemotherapy treatment. The best thing for patients who are undergoing chemotherapy to do is to discuss all the precautions and interactions with their physicians. Usually a patient's doctor will provide patient education pamphlets regarding chemotherapy treatment. Pamphlets are also available from local cancer centers and the American Cancer Society.

Hereditary angioneurotic edema

Definition

Hereditary angioneurotic edema (HANE) is a non-sex-linked (autosomal) dominant disease that results from mutations in a gene responsible for producing one of the proteins responsible for human immunity. This disease is also known as hereditary angioedema (HAE) or hereditary C1 inhibitor deficiency because it is a deficiency of the protein (C1-INH) that inhibits the action of the enzyme known as C1, which causes this disease.

Description

There are two recognized forms of HANE. Type I represents approximately 80%–85% of the cases of hereditary angioneurotic edema. In this type, the protein C1-INH is not produced in sufficient quantities. Type II HANE represents the remaining 15%–20% of cases. In this type, C1-INH concentrations are normal, but the C1-INH protein produced is defective.

Related to the two types of hereditary angioneurotic edema are acquired types of this disease (acquired angioneurotic edema [AANE] and acquired angioedema [AAE]) that are not based on a defective gene. Type I AAE is caused by a disorder that causes overgrowth (proliferation) of the lymph tissues and destroys C1-INH. Type II AAE is caused by the presence of autoantibodies (antibodies that attack the host organism that produced them) that destroy C1-INH. Both of these acquired forms of angioedema can generally be differentiated from the two types of HANE by the age of onset. Symptoms of the acquired diseases usually do not occur until the fourth decade of life, while those of the hereditary forms are generally present prior to puberty.

The human body has two distinct immune systems: the innate (nonspecific) immune system and the adaptive (specific) immune system. The complement system is a part of the innate immune system. The complement system uses at least 30 different proteins to “mark” any foreign cells in the body that do not have certain protective proteins on their cell membranes, which identify them as belonging in the body. These complement proteins are designated C1, C2, C3, etc. Once the foreign cells have been “marked,” a particular form of white blood cell, called a phagocyte, is dispatched to the area with the marked cells and destroys them.

Phagocytes will eventually destroy any cell that is marked by complement; therefore, it is important to make sure that the complement proteins are not marking non-foreign cells. When cells are improperly marked, these

cells will also be destroyed, causing what is called an autoimmune response. In effect, this autoimmune response means that the body is recognizing itself as foreign and attempting to destroy healthy cells. Inhibitors of the various complement proteins are necessary to prevent these proteins from marking the wrong cells or from continuing to mark cells after the foreign cells have been destroyed.

C1 inhibitor (C1-INH) is a chemical that is involved in the regulation of the complement system by inhibiting the action of the first complement protein (C1). C1-INH acts by binding free C1 molecules in the humor, preventing them from being able to function. It also limits the activation of other complement proteins.

Because C1-INH is diminished or defective in people affected with HANE, C1 is not inhibited and this inappropriately initiates the complement reaction that causes the swelling (acute inflammatory response) characteristic of HANE.

C1-INH also binds to the chemicals kallikrein and plasmin that are involved in blood clotting. Kallikrein is necessary for the activation of chemicals that cause dilation of blood vessels to allow increased blood flow to an area that requires more blood than normal. Plasmin is the chemical responsible for dissolving blood clots. A lack of binding of plasmin means that the formation of initial blood clots is difficult, a problem that is exacerbated by high levels of unbound kallikrein, which allows higher than normal blood flow.

With the absence or dysfunction of the C1-INH protein, the functions of blood flow, blood clotting, and immune response are impaired in individuals affected by hereditary angioneurotic edema, leading to swelling of the bodily tissues.

Genetic profile

The central Pyncheon family in Nathaniel Hawthorne's *The House of the Seven Gables* carries an ancestral curse of dying from choking on their own blood. Hawthorne describes members of the family who made odd sounds in the throat and chest when agitated and sometimes died from choking: “This mode of death has been an idiosyncrasy with his family, for generations past.... [The] prophecy was probably founded on a knowledge of this physical predisposition in the Pyncheon race.” It seems possible that Hawthorne was not only describing the symptoms of HANE but also acknowledging it to be an inherited genetic disorder.

All hereditary forms of HANE are caused by mutations in the gene responsible for the production of C1-INH. This gene is located on the long arm (q) of chromosome 11, at the specific location q11.2-q13. There are at

KEY TERMS

Acquired angioneurotic edema—Abbreviated AANE, or AAE, a nonhereditary form of angio edema that generally begins to show symptoms in, or after, the fourth decade of life.

Androgens—A group of steroid hormones that stimulate the development of male sex organs and male secondary sexual characteristics.

Angioneurotic edema—Recurrent episodes of swelling of the tissues of the body caused by an overactive immune system. This is also called angioedema.

C1 inhibitor—Abbreviated C1-INH, a protein that is responsible for preventing the action of the C1 complement molecules in the body. It is this protein that is either deficient or malformed in HANE.

Complement system—Class III MHC (major histocompatibility complex) proteins capable of destroying invading organisms directly via natural immunity, as well as indirectly through an interaction with other components of the immune system.

Hereditary angioneurotic edema—Abbreviated HANE, or HAE, an inherited kind of angioneurotic edema. Type I HANE is caused by a deficiency of C1-INH. Type II HANE is caused by a malformation of the C1-INH protein.

Kallikrein—A protein necessary for the activation of chemicals that cause dilation of blood vessels to allow increased blood flow to an area that requires more blood than normal. It is also capable of cleaving the complement, C5, into C5a, a much more robust and active form of this complement molecule.

Phagocyte—White blood cells capable of engulfing and destroying foreign antigen or organisms in the fluids of the body.

Plasmin—The blood protein that is responsible for dissolving blood clots.

Urticaria—Also known as hives. Usually associated with an allergic reaction.

least 13 different mutations of the *C1-INH* gene that cause the symptoms of HANE. Six of these are known to cause type I HANE, while another six are known to cause type II HANE. The final mutation has only been found in one individual. In this case, an acquired form of angioedema was determined to be caused by a mutation in a different region of the C1-INH gene than those mutations causing type I or type II cases of HANE.

Demographics

HANE affects approximately 50,000 people in the United States and Europe. It is estimated to occur in approximately 1 in every 50,000 to 150,000 live births. HANE appears to affect males and females equally and does not have a racial preference.

As an autosomal dominant trait, only one copy of an abnormal gene needs to be inherited for an individual to be affected. Therefore, if one child is affected with HANE, the likelihood that a second child will be affected with HANE is 50%. In cases of parents related by blood (consanguineous parents) the likelihood of HANE is increased.

Signs and symptoms

Individuals affected with either form of HANE have episodes of swelling of the hands, feet, trunk, face, digestive tract, and airways (angioneurotic edema or angioedema). These attacks of angioedema are often accompanied by attacks of nausea, vomiting, and abdominal pain. The frequency and severity of these attacks is not predictable and varies from individual to individual. These attacks may occur without cause, or they may be triggered by anxiety, stress, or minor traumas, such as dental procedures. If these symptoms are accompanied by hives (urticaria) a diagnosis other than HANE is indicated.

Symptoms of HANE generally first occur prior to puberty and episodes generally increase in severity after puberty.

Diagnosis

A diagnosis of HANE is suspected in individuals who have recurrent attacks of swollen tissues (angioedema). Diagnosis of type I HANE is confirmed by blood tests showing abnormally low levels of C1-INH, C2, and C4. Diagnosis of type II HANE is confirmed by blood tests showing normal levels of C1-INH and C2 but abnormally low levels of C4. Abnormally low levels of C1-INH and C4 without the presence of autoantibodies suggest a diagnosis of type I acquired angioedema, while abnormally low levels of C1-INH and C4 and the presence of autoantibodies suggest a diagnosis of type II acquired angioedema.

Hives (urticaria) are not generally associated with HANE. If hives are present with tissue swelling, this may suggest an allergic reaction, not a case of HANE. Occasionally, individuals affected with HANE also develop hives, but they are usually secondary to the angioedema. In a severe allergic reaction, hives are generally prominent as the major symptom.

Treatment and management

The treatment of both hereditary forms of angioedema is the same. Androgens (male sex hormones) such as winstrol, danazol, and oxandrolone have been shown to be effective in preventing chronic recurrences of swelling. These drugs are seldom used to treat acute attacks. In instances of abdominal attacks, fluid replacement therapy via intravenous injection may be required. Demerol and Compazine suppositories are often prescribed to relieve abdominal pain and vomiting.

Edema (swelling) of the airways is the most life-threatening feature of HANE. Without prompt medical attention, individuals affected with HANE can die from an obstruction of the airway caused by this swelling. Unfortunately, if the attending physician does not recognize HANE, attempts at tracheal intubation (formation of an airway directly in the neck) may aggravate the swelling rather than produce a functioning airway.

Treatment with vapor-heated C1-INH concentrate has proven to be an effective treatment both as a prophylactic (preventive) and a treatment for acute attacks of angioedema in all individuals affected with HANE. The C1-INH concentrate is derived from human blood plasma; therefore, it may possibly be contaminated. It is vapor-heated to inactivate possible hepatitis and HIV. However, because HANE is a disease of the immune system, many doctors are reluctant to use C1-INH from other people, and many patients are unwilling to accept such a treatment. The use of human recombinant C1-INH should alleviate any concerns arising from possible contamination of the blood supply.

Androgens are still the preventive treatment of choice because they are more cost-effective than treatments with C1-INH. However, androgens should not be given to women who are pregnant or who might become pregnant. In these cases, C1-INH treatment is required.

In 1999, the U.S. Food and Drug Administration (FDA) granted Orphan Drug Designations to human recombinant C1-INH for both preventive and acute treatment of HANE. On March 21, 2000, Baxter Healthcare's Hyland Immuno division and Europe's Pharming Group announced an agreement to jointly develop recombinant human C1-INH. Because of the Orphan Drug Designations from the FDA, this treatment for HANE was automatically fast-tracked and approved for human use in 2007.

Prognosis

The key to successful management of HANE is a proper medical diagnosis. With proper medical treatment, HANE is completely controllable, and individuals

affected with HANE have no diminishment in quality of life.

Hereditary colorectal cancer

Definition

Hereditary colorectal cancer (CRC) is cancer of the colon or rectum that develops chiefly as a result of inherited gene variants.

Description

The colon, or the large intestine, is a long, muscular tube that absorbs water from stool and advances the stool toward the rectum. The rectum works in conjunction with the anus to coordinate the process of defecation. The colon and rectum are jointly referred to as the colorectum.

A colectomy specimen displaying poorly differentiated metastatic endometrial malignant adenocarcinoma. (*Boilershot Photo/ Science Source*)

Colorectal cancer is a relatively common cancer. It results from tumors that start on the inner wall of the colorectum (mucosa) and first grow inwardly. Eventually, the tumor spreads outwardly until it reaches lymph nodes or other organs in the abdomen. Ultimately, cancer cells may detach from the original tumor and spread to distant parts of the body, such as the liver, lungs, bone, and brain. This is called metastasis.

Colorectal cancer arises from polyps on the colon. A polyp is a growth made up of tissue from the inner lining of the colon (mucosa). An adenomatous polyp (adenoma) is derived from the glandular elements of the mucosa. This type of polyp is the most common type associated with colorectal cancer. The more adenomas someone has, the more likely that one of them will transform into cancer. The larger the size of an adenoma, the more likely it will become cancerous. Early detection and removal of non-cancerous polyps is important since it decreases the risk of colorectal cancer.

In order for the adenoma to transform into a cancer cell, genes in a cell in the adenoma need to change (mutate). Usually cancer occurs from multiple mutations over time. That is why cancer happens more frequently in people who are older. Genes contain the instructions for the production of proteins. Proteins control the functioning of the cells of the body. A mutated gene will produce an abnormal protein that can cause the cells to multiply uncontrollably and become cancerous. In most cases, the mutation is caused by environmental factors like smoking, UV radiation, or age.

Some people can inherit a mutation (pathogenic variant) in a gene that makes them more likely to get colorectal cancer, because the pathogenic variant is in every cell of their body. These variants may also increase the risk for other cancers. Not all people with one of these variants will get colorectal cancer, since they have another backup copy of the gene without the variant. These variants can be passed down in the family. The two most

COLON/RECTAL CANCER

Cancers of the colon and rectum are among the commonest cancers in developed countries.

common categories of inherited colorectal cancer syndromes caused by a pathogenic variant are 1) polyposis syndromes, which include familial adenomatous polyposis and MUTYH-associated polyposis, and 2) Lynch syndrome.

Familial adenomatous polyposis (FAP)

People with familial adenomatous polyposis (FAP) develop adenomas in the colon and rectum at an average age of 15. Eventually, they will have hundreds to thousands of adenomas. The presence of such a large number of adenomas ensures that at least one of these adenomas will develop into cancer if the colon is not surgically removed. In people with FAP, the average age of occurrence of colorectal cancer is 39. Some patients will develop cancer in their teens, and almost every patient will have cancer by age 45.

Other types of polyps are also common in patients with FAP. Polyps may develop in the stomach or duodenum. Those in the stomach are benign, while those in the duodenum may become cancerous (malignant). The cancer risk in these other polyps is much less than the risk associated with colorectal polyps. FAP is caused by pathogenic variants in the *APC* gene

Three variants of FAP have been identified:

- Gardner syndrome is a rare variant of FAP characterized by colorectal polyps and a marked prominence of

growths that occur outside the intestine. Examples of these growths include non-cancerous bone tumors, harmless bumps under the skin, and non-cancerous connective tissue (desmoid) tumors. Although these growths usually present only cosmetic problems, desmoid tumors can occasionally compress nearby tissue in a harmful way. People with Gardner syndrome can also have extra teeth and a pigmented spot in the eye.

- Turcot syndrome is another rare type of FAP. Patients with this syndrome have the typical colorectal polyps as well as malignant tumors of the central nervous system, such as medulloblastoma, astrocytoma, ependymoma, and glioblastoma multiforme.
- Attenuated adenomatous polyposis is a milder form of FAP. Patients with this type have many colonic polyps but not the hundreds or thousands seen in typical FAP. The chance of developing colorectal cancer approaches but does not reach 100%, and colorectal cancer usually appears later than in patients with typical FAP.

MUTHYH-associated polyposis

MUTHYH-associated polyposis (MAP) is associated with mutations of the *MUTHY* gene. Much like FAP, MAP is characterized by the formation of many polyps in the colon. People with MAP tend to have fewer than 100 polyps, far fewer than what is seen in FAP. Individuals with MAP are at a greater risk of developing tumors in the upper gastrointestinal tract. Polyps and tumors develop, on average, by age 50.

Hereditary nonpolyposis colorectal cancer

Hereditary nonpolyposis colorectal cancer (HNPCC) is also known as Lynch syndrome. People with Lynch syndrome have more polyps than average, but not the hundreds or thousands of polyps associated with FAP. Frequently, a patient with Lynch syndrome will have multiple cancers at the same time (synchronous) or may develop cancers at different time periods (metachronous). The age of onset of colorectal cancer likely varies by type of pathogenic variant. Some research suggests that the average age of onset is in the 40s, while other studies have found that men have a median age of onset of 54 years, while women have a median age of onset of 70 years. Men with Lynch syndrome have about a 22% to 75% risk, while women have a 20% to 52% risk of colorectal cancer. The risk that someone with Lynch syndrome will get colorectal cancer also depends on which gene variant they have.

People with Lynch syndrome are at increased risk for other cancers. Women with Lynch syndrome have a 12% to 46% chance of getting cancer of the lining of the uterus (endometrial cancer). They also have a 3% to 17% chance

of ovarian cancer. Men and women with Lynch syndrome also have an increased risk for stomach, kidney, bladder, brain, and possibly breast cancer. Muir-Torre syndrome is a rare form of Lynch syndrome. In addition to polyps and cancer of the colon and rectum, patients exhibit various types of skin cancer. Lynch syndrome is caused by pathogenic variants in a group of genes that help repair DNA called the mismatch repair genes (MMR).

Genetic profile

Colorectal cancer is caused by a combination of genetic and environmental factors. We all inherit variants (mutations) in our genes that may have influence on our risk of getting cancer. Some of these variants might increase our risk, while others might decrease it. Some people inherit a major pathogenic gene variant that can significantly increase their risk for getting colorectal and possibly other cancers. Individuals with this pathogenic gene variant have what is called a colon cancer syndrome. This does not necessarily mean that they will get cancer, as their risk will be affected by environmental factors and other genes.

One study found that about one in six (16%) people with colorectal cancer have a pathogenic variant in a gene that predisposed them to colorectal cancer. If someone has relatives (especially young relatives) with colorectal cancer, that increases the chances that there is a major pathogenic variant in the family. However, someone can have inherited a pathogenic variant that increases their risk of colorectal cancer and not have a significant family history. One study found that 60% of people with a pathogenic colorectal cancer variant did not have a significant family history of cancer, because not all people who inherit the pathogenic variant will get cancer, or it might happen later in life. Pathogenic variants associated with colorectal cancer often increase the risk for other cancers as well.

Colorectal cancer is linked to pathogenic variants in proto-oncogenes, tumor suppressor genes, DNA mismatch repair genes, and modifier genes. These variants can be inherited and/or occur spontaneously. Proto-oncogenes help regulate cell growth. A pathogenic variant in a proto-oncogenes turns it into an oncogene, which is less effective at regulating the cell. This can make a cell more likely to become cancerous. Examples of proto-oncogenes are K-ras, src, and c-myc. Tumor suppressor genes normally help prevent cancer from developing in a cell. variants in tumor suppressor genes make the cell more likely to become cancerous. Examples of tumor suppressor genes are the *APC*, *TP53* (p53), *STK11* (*LKB1*), *PTEN*, *BMP1A*, and *SMAD4* (*MADH/DPC4*) genes. The mismatch repair genes are *MLH1*, *MSH2*,

MSH6, *PMS2*, *EPCAM* (*TACSTD1*, *MYH*(*MUTYH*), *POLD1*, and *POLE*. Modifier genes affect other genes. Pathogenic variants in modifier genes can affect the functioning of other genes, which in turn can result in an increased risk of cancer. Examples of modifier genes are the *COX2* gene, the *CD44v* gene, and the *phospholipase A2* gene.

FAP genetics

FAP results from pathogenic variants in the *APC* gene. The *APC* gene is a tumor suppressor gene. It is an autosomal dominant condition, which means that an individual with FAP has inherited a pathogenic variant in one copy of their *APC* gene. This pathogenic variant is in all cells of their body. If the other copy of the *APC* gene spontaneously gets a pathogenic variant in one of their cells, that cell will be more likely to become cancerous. Individuals with a pathogenic variant in the *APC* gene have a 50% chance of passing it on to their offspring.

MUTHYH-associated genetics (MAP)

MAP is caused by pathogenic variants in the *MUTHY* gene. It is inherited in an autosomal recessive pattern. Individuals with MAP have inherited a pathogenic variation in both copies of their *MUTHY* gene. They have inherited a pathogenic variant from each of their parents. Their parents are carriers, which means that they have a 25% chance of having a child with MAP, a 50% chance of having a child who is a carrier, and a 25% chance of having a child without a pathogenic variant in their *MUTHY* gene. All children of individuals with MAP will be at least carriers. Carriers have a slightly increased risk of colorectal cancer.

Lynch Syndrome genetics

Lynch Syndrome is most commonly caused by pathogenic variants in mismatch repair genes *MLH1*, *MSH2*, *MSH6*, or *PMS2* or a piece missing of the *EPCAM* gene. The *EPCAM* gene is not a mismatch repair gene, but pieces missing in this gene can inactivate the *MSH2* mismatch repair gene. Not all gene variants associated with this syndrome are known. Lynch syndrome is autosomal dominant, which means that individuals how have it have a pathogenic variant in one copy of their gene, while the other copy is normal. They have a 50% chance of passing on Lynch syndrome to their children.

Genetic Testing

It is recommended that everyone with colorectal cancer have their tumor tested to see whether there is instability in the tumor, (MSI) which is a sign of Lynch

KEY TERMS

Adenomatous polyps (adenomas)—A growth in the colon that may become cancerous if not removed.

Desmoid tumors—Abnormal growths found in the connective tissue of the body.

Duodenum—The first segment of the small intestine.

Epidermoid cysts—Harmless cysts that occur on the skin.

Extra-intestinal—Outside of the intestine.

Neoplasm—An abnormal growth in tissues of the body, caused by rapidly multiplying cells.

Osteoma—A bony tissue tumor, either benign or malignant.

syndrome. If this instability is found, then genetic testing for Lynch syndrome would be recommended. MMRpro, MMRpredict, and PREMM5 (PREdiction Model are three validated computer models that estimate risk for Lynch Syndrome. Genetic testing is recommended for individuals with a risk of 2.5% or greater on PREMM5 or 5% or greater on MMRpro and MMRpredict.

Genetic testing can also be done on a family member with colorectal cancer to see whether they have a pathogenic variant in any of the genes associated with colorectal cancer. At-risk family members can then be tested to see whether they have inherited this same variant. Genetic testing can detect a pathogenic variants in approximately 60% to 80% of FAP families and about 50% of Lynch syndrome families. If no family member with cancer is available for testing, then someone without cancer can be tested. If no variant is detected in this person, then it is still possible that others in the family have a variant. Although genetic testing can provide useful information, it may be associated with psychosocial risks. Genetic counseling is therefore recommended.

Extrachromosomal Drivers of Cancer

Some tumors seem to have bits of DNA that are found outside of the chromosome, called extrachromosomal DNA (ecDNA). The ecDNA is separate from the DNA found in the 46 chromosomes that contain the genes inherited from our parents. The ecDNA often includes multiple cancer-triggering genes, called oncogenes, and genes that are involved in tumor formation and progression. The ecDNA can make the cancer more aggressive and more resistant to treatment. Cancer patients with ecDNA appear to have a significantly shorter survival

time. EcDNA appears to be unique to cancer and found in at least 14% of human tumors.

Demographics

Colorectal cancer is relatively common, with approximately 160,000 new cases diagnosed each year. One study found that about one in six (about 16%) of people with colorectal cancer have a syndrome that results from a pathogenic variant. The incidence of all colorectal cancer increases with age.

Signs and symptoms

The clinical manifestations of colorectal cancer depend largely on location and tumor size. Tumors in the proximal colon can grow large before detection. They may cause weight loss, abdominal pain, or bleeding. The bleeding may be readily noticed by the patient as frank blood in the toilet or smears of blood in the stool. Less-extensive bleeding may be detected by the fecal occult blood test, in which a sample of stool obtained during a rectal exam is tested for microscopic amounts of blood. Anemia, or low red blood cell count, detected by a laboratory test may prompt further examination of the colon to determine whether a tumor is the source of bleeding. In the smaller, distal colon, tumors are more likely to cause obstruction, which in turn may cause gas pains and decrease in the caliber of the stool. Additionally, these cancers may cause bleeding or a change in bowel habits. In FAP, the first symptom is usually diarrhea.

Diagnosis

The presence of symptoms such as abdominal pain, weight loss, change in bowel habits, or decrease in stool caliber may point to a diagnosis of colorectal cancer. Of course, these symptoms must be interpreted within the context of the patient's age, previous medical history, and family history of colorectal cancer.

Ideally, the diagnosis of colorectal cancer should be made before symptoms develop. A number of screening tests are useful for detecting colorectal cancer. The fecal occult blood test is a simple test performed in the doctor's office. The normal result is the absence of blood in the stool. If blood is found in the stool, the suspicion for colorectal cancer becomes higher.

Standard screening also includes an endoscopic exam—either sigmoidoscopy or colonoscopy. In these exams, a thin, specially lighted tube is inserted directly into the anus and advanced into the colon. The physician can view the inside of the colon and check for polyps or tumors. Sigmoidoscopy allows examination of the lower part of the colon, while colonoscopy allows a more extensive view. Sometimes a barium enema is added to the

QUESTIONS TO ASK YOUR DOCTOR

- I have a family member with colorectal cancer; do I need to get a screening test?
- If I have colorectal cancer, what are my treatment options?
- Should I get a second opinion? How do I do that?
- What risks and side effects should I expect from testing or treatment?
- If I need treatment, what should I do to get ready?

screening procedure. In that test, a dye is injected into the anus and up into the colon. The dye coats the inside of the colon so that tumors can be detected by plain x-ray.

New screening tests are currently under investigation. In wireless endoscopy, a pill-sized camera is swallowed. As it traverses the gastrointestinal tract, it transmits video footage that can be examined for suspicious abnormalities. Eventually, the camera is passed out of the anus with the stool. Virtual colonoscopy generates a three-dimensional image of the colon by applying advanced computer graphics technology to images obtained by computed tomography (CT) scanning. These processes can spare the patient the usual discomfort of traditional endoscopy. However, they are not yet fully developed nor approved for colorectal cancer screening.

If any of the screening tests identifies an abnormality that appears to be a tumor, the diagnosis must be confirmed by biopsy, which is performed during colonoscopy. A small piece of tissue is removed and examined in the laboratory for cancerous cells.

Most medical organizations recommend that screening begin in the general population at age 40 to 50. The fecal occult blood test is performed annually, and sigmoidoscopy every three to five years. If a first-degree relative has colorectal cancer, then screening should begin at age 35 to 40. Alternatively, screening can begin five years earlier than the age of a young relative who has had colorectal cancer.

Individuals in families affected by hereditary colorectal cancer syndromes are at increased risk for developing cancer early in life. Therefore, screening is initiated at a young age. It can be reserved for those family members who have been proven by genetic testing to carry the abnormal gene, or it can be applied to all family members if the specific mutation cannot be identified. Some experts propose that in families with a history of FAP, screening should begin at age 10 to 12 and be repeated

every one to two years. In families with Lynch syndrome, colorectal screening should begin at age 20 to 30 and be repeated every one to two years.

Since FAP and Lynch syndrome are associated with other cancers, affected patients should undergo appropriate screening for those malignancies as well. Those with FAP require regular upper endoscopy to detect tumors of the stomach and duodenum. Women with Lynch syndrome should undergo screening for uterine cancer by way of random biopsies of the inner lining of the uterus.

Factors that make it more likely that someone has inherited a pathogenic variant that predisposes them to colorectal cancer are:

- many people in the family with colorectal cancer or polyps
- more than one cancer in a patient with colorectal cancer
- other cancers associated with colorectal cancer syndromes, such as endometrial cancer; and
- early onset of colorectal cancer

Treatment and management

The treatment of sporadic colorectal cancer requires surgical removal of the tumor and surrounding tissue. Chemotherapy or radiation therapy may also be necessary. Treatment of colorectal cancer in the hereditary syndromes is more aggressive. In these cases, the entire colon must be removed, since cancer will almost certainly develop in any remaining colon. Sometimes the rectum is also removed; alternatively, the patient may undergo frequent examination of the rectum for polyps or cancers. Experts strongly recommend that individuals with known FAP consider surgical removal of the colon and/or rectum early in life as a prophylactic measure, before cancer is diagnosed. Although the role of prophylactic surgery in patients with Lynch syndrome is less well defined, many experts favor it. The patient faces a choice between prophylactic surgery and frequent, lifelong screening.

Some studies have shown that the drug sulindac may reduce the number of adenomatous polyps that develop in FAP and its variants. In addition, certain nonsteroidal anti-inflammatory drugs such as aspirin may reduce the incidence of colorectal cancer in general.

Prognosis

Patients with a hereditary colorectal cancer syndrome such as FAP, Lynch syndrome, or its variants have a much higher likelihood of developing colorectal cancer than the general population. Individuals with FAP or MAP syndrome have close to a 100% chance of getting colorectal cancer if untreated. If colorectal cancer does develop, survival depends on the extent to which the

cancer has spread. Cancer that is isolated to the colon is associated with much better chances survival than cancer that has spread to distant organs such as the liver or lungs.

Hereditary coproporphyrria

Definition

Hereditary coproporphyrria is a genetic disorder that may cause abdominal pain, sometimes accompanied by extreme sensitivity to sunlight and skin problems associated with photosensitivity. Up to half of the individuals who have this disorder experience very mild or no symptoms.

Description

Hereditary coproporphyrria (HCP) is one of a group of at least eight disorders collectively known as porphyria. Although the eight disorders have many differences, they do share an underlying characteristic: In all of them, chemicals known as porphyrins or porphyrin precursors (substances that will become porphyrins) build up to abnormally high levels in the body. The disorders differ from one another in the specific porphyrin or porphyrin precursor that accumulates.

In hereditary coproporphyrria, the accumulating chemical is coproporphyrin (especially coproporphyrin type III). It results because of a mutation in the gene that carries the instructions for making a certain enzyme, known as coproporphyrinogen oxidase. Normally, coproporphyrinogen oxidase participates in one of the steps of heme production. Heme is a compound that is an essential component of hemoglobin and other iron-containing proteins in the body. Hemoglobin delivers oxygen through the blood and to the body's cells. Coproporphyrinogen oxidase is necessary for the step in the pathway that speeds the conversion of coproporphyrin to another compound (protoporphyrinogen), which then continues through other steps to eventually yield heme. In most

KEY TERMS

Coproporphyrin—Excrement in the urine or feces indicative of unused porphyrin in the body due to overaccumulation of porphyrin.

Heme—The deep red iron-containing prosthetic group $C_{34}H_{32}N_4O_4Fe$ of hemoglobin and myoglobin that is a ferrous derivative of protoporphyrin and readily oxidizes to hematin or hemin.

Photosensitivity—Sensitivity to light.

Porphyrin—Chemicals involved in the production of heme.

cases, coproporphyrinogen oxidase enzyme activity is reduced by 50%.

When a person has a mutation in this gene, too little coproporphyrinogen oxidase is produced, and the heme-production pathway does not work as it should. Since the enzyme is specifically connected to the step that converts coproporphyrin type III, this chemical does not go through its conversion quickly enough and can build up to unhealthy levels. Such an accumulation can lead to various symptoms, including abdominal pain and nausea, a fast pulse, dark-colored urine, and skin sensitivity. Not all persons who have the mutated gene have these, or indeed any symptoms, so some people with this disorder experience few, if any, problems.

Porphyrins, including coproporphyrin, are chemicals that are involved in the chemical process by which the body produces heme. In hereditary coproporphyria, a genetic mutation hinders one of the chemical-conversion steps in the heme-production pathway: the step that would otherwise convert coproporphyrin. When this happens the pathway makes coproporphyrin as it should, but the coproporphyrin does not then convert quickly enough into the chemical that is needed for the next step along the way. As a result, coproporphyrin accumulates, and associated symptoms may develop. Besides coproporphyrin, two other precursors of coproporphyrin also accumulate: porphobilinogen and amino-levulinic acid.

Hereditary coproporphyria is a rare autosomal dominant disorder, which means that individuals can inherit it if just one of their parents has the mutated gene.

An even rarer form of this disease is known as harderopporphyria. Individuals with this disorder are homozygous for the mutated gene. In other words, they have inherited a mutated gene from each of their parents. Individuals with this condition have neonatal hemolytic

anemia, a condition in which too few red blood cells are present in the blood.

Genetic profile

HCP is an autosomal dominant genetic mutation. A mutation in the *CPOX* gene causes coproporphyria. Located on the long arm of chromosome 3, the *CPOX* gene carries the blueprint for making the enzyme coproporphyrinogen oxidase that plays an important role in the production of heme, which is a vital protein. Mutations in this gene produce coproporphyrinogen oxidase that does not work as well as it should and, consequently, the heme-production pathway suffers.

Scientists have identified at least 45 mutations of the *CPOX* gene that cause hereditary coproporphyria. In some cases, the mutations involve the switch of a single amino acid (amino acids are the building blocks of proteins).

Because hereditary coproporphyria is an autosomal dominant disorder, adults with the mutated gene have a 50% chance of passing it to each child they may have. If both parents have the disorder, their child has a 25% chance of inheriting two copies of the mutated gene, which results in the very rare homozygous form of the disease called harderopporphyria.

Demographics

Hereditary coproporphyria is a very rare genetic disorder. It is not associated with a higher incidence in any geographic location, any ethnic group, or either gender. Harderopporphyria is an even rarer form of this hereditary coproporphyria. As of 2013, the incidence of HCP had been documented as .3 per 100,000 in Europe.

Signs and symptoms

Many individuals with hereditary coproporphyria—up to half—have no noticeable symptoms. The typical symptoms, when they do occur, vary from one individual to the next, and may include the following: Photosensitivity (sensitivity to sunlight, sometimes even sunlight through a window) that can lead to burning, blistering, and scarring of the exposed skin; dark-colored urine, or urine that darkens when it is left standing; increased pulse/heart rate; pain, especially in the abdomen and back; and nausea, vomiting, and constipation. Neurological symptoms may also be present including motor dysfunction and/or central nervous system dysfunction.

There are additional symptoms, although extremely rare (especially when the patient receives proper treatment and takes precautionary measures): muscle

QUESTIONS TO ASK YOUR DOCTOR

- How will I know when an attack is coming on?
- Are there support groups for me and my family?
- What treatment options are right for me?

weakness; paralysis of respiratory muscles, sometimes resulting in death; dizziness; and hallucinations.

Also, patients with harderoporphyrria may experience neonatal hemolytic anemia.

Diagnosis

Diagnosis can be difficult, because a patient's symptoms can often be attributable to a variety of disorders and are not specific to hereditary coproporphyrria. The diagnosis of HCP can be determined via physical examination, laboratory testing, and genetic confirmation of a *CPOX* gene mutation.

Examination

The suite of symptoms in a particular patient may lead a doctor to suspect a range of disorders, possibly including hereditary coproporphyrria. A family history will aid in the preliminary diagnosis.

Tests

The doctor may order various laboratory tests to check for the presence of high levels of coproporphyrin, porphobilinogen, and/or amino-levulinic acid in the blood, urine, or stool. These tests are often given during an acute attack of HCP. The test for fecal coproporphyrin is especially diagnostic.

Treatment and management

There is no cure for HCP. Treatment and management of the clinical manifestations of HCP are available, however. Doctors recommend various precautionary measures to reduce acute attacks. These measures may include the avoidance of sunlight, fasting, and certain drugs or alcohol, as well as the use of effective sunscreens. Doctors may recommend increased water intake or other measures to counter some of the effects of vomiting. Particularly acute abdominal pain may result in a hospital stay, although this is rare for hereditary coproporphyrria. In addition, a doctor may prescribe medications to help treat abdominal pain. Individuals may

receive hemin therapy by way of intravenous injection. Hemin therapy is a negative feedback therapy on the heme pathway and is widely administered in the early stages of an attack and also as a weekly infusion to help with hemoglobin production and function.

Before taking drugs for other maladies, patients should consult their doctor to ensure that the drugs will not promote an attack.

Due to a link between acute attacks and the menstrual cycle, attacks can be prevented in women by suppressing menses with pharmaceuticals and refraining from oral contraception use.

Adults who have the disease may wish to undergo genetic counseling before deciding to have children so that they understand the risks.

Prognosis

Up to one-half of the individuals with hereditary coproporphyrria experience no noticeable symptoms and live otherwise healthy lives. Of the remaining patients, symptoms range from mild to more severe. With proper precautions and medical intervention, when necessary, most individuals with this disorder do well.

Hereditary desmoid disease

Definition

Hereditary desmoid disease (HDD) is a condition that causes people to develop a benign (noncancerous) growth known as a desmoid tumor. Desmoid tumors may also be called aggressive fibromatosis. Other names for HDD include familial infiltrative fibromatosis (FIF) and desmoid-type fibromatosis.

Description

In HDD, multiple family members from several generations develop desmoid tumors. These tumors are very rare, accounting for less than 0.1% of all tumors diagnosed. The term “desmoid” comes from the Greek word for “band” or “tendon.” That describes these tumors well, as they have a tendon- or ligament-like appearance. Desmoid tumors arise from myofibroblasts, which are cells that form connective tissue but also have some of the characteristics of smooth muscle cells. Desmoid tumors usually occur in the abdomen, but they may also develop in the neck, chest, arms, and legs. In women, they may occur in the breasts.

Most desmoid tumors—more than 97%—are *not* hereditary. These tumors occur sporadically, meaning that they occur in random individuals and are not caused by germ-line genetic mutations. Germ-line genetic mutations are those that occur in the germ cells that give rise to sperm and ova and are thus passed on to offspring. Most nonhereditary desmoid tumors are caused by what are known as somatic mutations. Somatic mutations are acquired during the person’s lifetime; they occur in any body cell other than sperm or ova. They can cause disorders or diseases but are not passed on to the next generation. In 1999, a patient was identified with a somatic mutation in the *CTNNT1* gene on the short arm of chromosome 3 at 3p21. The gene codes for a protein called beta-catenin. About 85% of sporadic desmoid tumors are now known to be caused by mutations in the *CTNNT1* gene. Health problems associated with the *APC* gene mutation are not present in people who develop sporadic desmoid tumors. These people do not have a family history of desmoid tumors.

Hereditary desmoid tumors may appear due to mutations (changes) in a gene called adenomatous polyposis coli (*APC*), located on the long arm of chromosome 5 at 5q21-q22. Mutations in the *APC* gene usually result in a disorder called familial adenomatous polyposis (FAP). This condition causes hundreds to thousands of polyps (tiny growths arising from mucous membranes) to develop in the tissues lining the colon. FAP is associated with a high risk of developing colon cancer. People

diagnosed with FAP must have their health monitored on a regular basis. Colon cancer can be prevented by careful medical screening and removal of the colon.

Some families with FAP develop extra-colonic symptoms (involving organs other than the colon), including desmoid tumors. The combination of colon polyposis and desmoid tumor is sometimes called Gardner syndrome, but it is now known that the two conditions are the same. Other extra-colonic features seen in families with FAP are cysts in the jawbone, skin cysts (epidermal cysts), bony bumps on the skull, a specific kind of spot on the retina of the eye, and thyroid cancer. About 13% of people with FAP will develop desmoid tumors. However, the precise risk differs from family to family.

In HDD, multiple family members over two or more generations develop desmoid tumors but not colon polyposis. Family members in subsequent generations have an increased risk of developing desmoid tumors.

Genetic profile

HDD is inherited in an autosomal dominant pattern, which means that every person diagnosed with HDD has a 50% chance of passing on the condition to each of his or her children. The chances that a child who has the gene mutation associated with HDD will develop a desmoid tumor are thought to be very high, maybe even 100%. It is possible that there may be other genes involved in HDD, but no gene other than *APC* had been identified as of 2015. The location of the mutation within the *APC* gene may predict the symptoms and health problems that a person will experience, but this association is far from clear.

Demographics

Hereditary desmoid disease is a rare condition. As of 2015, only five families had been reported in the medical literature. It is likely, however, that not all families with HDD have been described in the literature. Males and females are equally affected. Sporadic desmoid tumors are diagnosed in about 900 people each year in the United States.

Signs and symptoms

Desmoid tumors may cause a noticeable lump in the affected part of the body and/or pain resulting from the compression of nerves, muscles, or such organs as the kidneys or lungs. The overlying skin, however, is not usually affected. Other symptoms of desmoid tumors may include fever, obstruction of the digestive tract, or difficulties in using the hands, legs, feet, or other affected part of the body. Patients with desmoid tumors in the legs or feet may walk with a limp.

KEY TERMS

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

De novo—Latin term for “new.”

Familial adenomatous polyposis (FAP)—An inherited syndrome causing large numbers of polyps and increased risk of colon cancer and other cancers.

Fibromatosis—The medical term for a group of conditions marked by benign soft-tissue tumors that are aggressive, infiltrate other tissues, and frequently recur even though they are not cancerous. HDD is sometimes categorized as a type of fibromatosis.

Gardner syndrome—A term that is sometimes used for patients with familial adenomatous polyposis (FAP) who have desmoid tumors in the tissues covering the colon in addition to polyps inside the colon.

Germ-line mutation—A heritable change in the DNA of a germ cell (a cell destined to become an egg or in the sperm). When passed from one generation to the next, a germ-line mutation is incorporated in every cell of the body.

Myofibroblast—A fibroblast (cell that forms connective tissue) that has some of the characteristics of a smooth muscle cell.

Polyp—A mass of tissue bulging out from the normal surface of a mucous membrane.

Somatic mutations—De novo mutations that are acquired throughout life and affect only some cells in the body.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

Diagnosis

HDD is usually diagnosed solely upon family history. Evaluation for HDD requires filling out a detailed, three-generation family tree. Medical records and/or death certificates should be examined to confirm or clarify possible diagnoses of desmoid tumors. Medical records for family members developing colon polyps and/or undergoing colon surgery are requested in order to evaluate for FAP.

Genetic (or diagnostic) testing for *APC* gene mutations (changes) is another way of making a diagnosis. It may be offered to someone who has developed a desmoid

tumor and has a family history of such tumors. If a mutation is identified, the positive test result confirms the diagnosis. If no mutation is identified, this negative test result does not necessarily exclude the diagnosis of HDD.

Diagnostic testing for HDD may be offered to an individual who has no personal history of a desmoid tumor but whose family history is strongly suggestive of HDD. Prenatal diagnosis of HDD is available only if an *APC* genetic alteration has already been identified in the family. Such predictive genetic testing is best done with a geneticist (a doctor specializing in genetics) and/or a genetic counselor.

Genetic testing for mutations in the *CTNNB1* gene is also available for patients with the nonhereditary form of desmoid tumor.

Treatment and management

There is neither a cure for HDD nor a method for preventing it. Treatment depends upon the location of the tumor and may include one or more of the following: surgery, chemotherapy, hormonal therapy, and/or radiation. Surgical treatment is often challenging because desmoid tumors are composed of dense tissue resembling scar tissue. They cling very tightly to the underlying organ and are difficult to remove completely. The rate of recurrence is about 50%; therefore, more than one operation is usually required to remove the tumor permanently.

Everyone diagnosed with a desmoid tumor should be evaluated for FAP. This evaluation includes a detailed family history as well as colon screening through sigmoidoscopy or colonoscopy.

Treatment is not required until a tumor develops. Someone who has symptoms, however, must have regular medical check-ups.

There are no proven methods of screening for or preventing desmoid tumors, but it is suggested that people with or at risk for HDD have physical examinations every year. It is very important that an individual's physician be aware of the family history and the risk of developing a tumor.

Prognosis

An individual who has a genetic mutation for HDD has a high chance of developing a desmoid tumor. However, the tumor itself is treatable. Prognosis may be affected by a person's overall condition, so being healthy and engaging in healthy behaviors increase the chances of a good outcome. Some researchers think that HDD may increase a person's risk of other types of cancer, but this association was not known for certain as of 2015. It is also not known whether HDD affects a person's life expectancy.

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever seen or treated a patient with either HDD or a sporadic desmoid tumor?
- What treatments would you recommend for a patient diagnosed with HDD?
- Are there any investigative treatments available for HDD?
- Would you recommend genetic testing for either HDD or a sporadic desmoid tumor?

Hereditary hearing loss and deafness

Definition

Hereditary hearing loss and deafness are caused by inherited genetic factors. It is estimated that 50% of congenital (present at birth) and severe early-onset deafness have genetic causes. More than 400 inherited genetic

syndromes are involved in hearing loss and deafness (syndromic). Hearing loss and deafness can also be inherited without an underlying genetic syndrome (nonsyndromic).

Description

In normal hearing, sound vibrations enter the large fleshy external part of the ear (the pinna) and travel down the auditory canal striking the eardrum (tympanic membrane), which begins to vibrate. As this membrane vibrates, it touches the first of a series of three small bones (the malleus, the incus, and the stapes) that mechanically transfer the vibrations to the cochlea. The cochlea is a fluid-filled tube that bends back on itself such that the two open ends lie on top of each other. One end is covered by a membrane called the oval window, and the other end is covered by a membrane called the round window. The oval window is struck by the stapes. Since the cochlea is filled with fluid, the oval window cannot vibrate without the assistance of the round window: as the oval window is pushed in by the stapes, the round window bulges out; as the oval window oscillates out, the round window bulges inward.

The vibrations imparted to the oval window and the round window are picked up by the organ of Corti within the cochlea. The organ of Corti consists of hair cells embedded in a gelatinous membrane (the tectorial membrane) that rests on the basilar membrane. Sensory neurons terminate at the hair cells of the organ of Corti. Vibration of the fluid in the cochlea causes the basilar membrane to move, which causes the hairs to bend, creating an electrical signal. This is picked up by the sensory neurons and transferred to the auditory (or cochlear) nerve, which sends the signal to the brain.
